Tax Distribution Pressure and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Tax Distribution Pressure (TDP), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by Novy-Marx and Velikov (2023). A value-weighted long/short trading strategy based on TDP achieves an annualized gross (net) Sharpe ratio of 0.37 (0.35), and monthly average abnormal gross (net) return relative to the Fama and French (2015) five-factor model plus a momentum factor of 39 (33) bps/month with a t-statistic of 3.65 (3.16), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Growth in book equity, gross profits / total assets, Long-term EPS forecast, Change in equity to assets, Operating leverage, Asset growth) is 25 bps/month with a t-statistic of 2.27.

1 Introduction

Asset prices reflect firms' production decisions and the frictions they face when adjusting capital and investment. In equilibrium, cross-sectional variation in expected returns arises from differences in firms' exposure to systematic risks that affect their marginal productivity and investment opportunities. Despite extensive research on production-based asset pricing models, we still lack complete understanding of which firm characteristics best capture variation in firms' conditional risk premia and their sensitivity to aggregate productivity shocks.

Tax Distribution Pressure (TDP) emerges as a novel predictor that potentially captures important aspects of firms' production dynamics and investment constraints. When firms face pressure to distribute cash for tax purposes, they experience binding constraints on their internal financing capacity, which directly affects their ability to respond to investment opportunities and productivity shocks. This mechanism creates systematic variation in expected returns that existing production-based factors may not fully capture.

In a production economy, firms maximize value by choosing optimal investment policies subject to adjustment costs and financing frictions Cochrane and Piazzesi (2005). Tax distribution requirements impose additional constraints on firms' cash retention policies, effectively increasing the shadow cost of internal funds and creating wedges between the marginal product of capital and the cost of external financing. These constraints become particularly binding during periods of high productivity growth when firms would otherwise prefer to retain earnings for investment Zhang (2005).

Firms facing high tax distribution pressure operate with reduced financial flexibility, making them more sensitive to aggregate productivity shocks. When positive productivity shocks arrive, constrained firms cannot adjust their capital stock as quickly as unconstrained firms, leading to foregone investment opportunities and lower future cash flows Livdan et al. (2009). This mechanism generates cross-sectional variation in firms' exposure to systematic risk, as financially constrained firms require higher expected returns to compensate investors for bearing this additional risk.

The production-based interpretation of TDP connects directly to conditional risk premia through the stochastic discount factor. In models with investment-based pricing kernels, firms with higher adjustment costs or tighter financing constraints load more heavily on the pricing kernel, generating higher expected returns Berk et al. (1999). Tax distribution pressure acts as a measurable proxy for these frictions, capturing variation in firms' marginal costs of production and their ability to respond to time-varying investment opportunities. The resulting cross-sectional spread in expected returns reflects compensation for bearing systematic risk related to aggregate fluctuations in productivity and investment conditions.

We find strong evidence that Tax Distribution Pressure predicts cross-sectional variation in stock returns. A value-weighted long-short strategy that buys high TDP stocks and sells low TDP stocks earned an average return of 36 basis points per month with a t-statistic of 2.84 over the 1967-2024 sample period. The strategy achieved an annualized Sharpe ratio of 0.37, placing it in the 80th percentile among 212 documented anomalies in the factor zoo.

The TDP strategy's performance remains robust after controlling for established risk factors. The strategy generated a monthly alpha of 39 basis points with a t-statistic of 3.65 relative to the Fama-French six-factor model. Even after controlling for the six most closely related anomalies—including growth in book equity, gross profits to total assets, and operating leverage—the strategy maintained an alpha of 25 basis points per month with a t-statistic of 2.27. These results demonstrate that TDP captures unique variation in expected returns not explained by existing factors.

The economic significance of our findings persists after accounting for transaction costs. The net Sharpe ratio of 0.35 ranks in the 93rd percentile among all anomalies, and the strategy generated positive net generalized alphas relative to all five standard factor models tested. Among the largest stocks, those with market capitalization above the 80th NYSE percentile, the TDP strategy earned 23 basis points per month with a t-statistic of 1.76. A dollar invested in the TDP strategy in 1967 would have grown to $5.46 by 2024 after transaction costs, ranking in the top 1% of all anomaly strategies.

Our study makes several contributions to the production-based asset pricing literature. While Fama and French (2015) document that investment and profitability factors help explain cross-sectional variation in returns, and Hou et al. (2015) propose a q-factor model based on investment theory, we show that tax-induced financial constraints provide additional explanatory power beyond these established factors. Our TDP measure captures a specific friction in firms' production functions that existing investment-based factors do not fully incorporate.

Methodologically, we extend the work of Novy-Marx and Velikov (2023) by demonstrating that TDP survives their comprehensive testing protocol for anomaly evaluation. Unlike many anomalies that lose significance after accounting for transaction costs or fail to predict returns among large stocks, the TDP strategy maintains economic significance across multiple robustness tests. Our finding that TDP improves the mean-variance efficient frontier even after controlling for transaction costs in both the test asset and benchmark factors represents a stringent test of economic value that few anomalies pass.

The broader implications of our findings extend to corporate finance and tax policy. By identifying tax distribution pressure as a systematic risk factor in asset prices, we provide evidence that tax-induced financial frictions affect firms' cost of capital and investment decisions in economically meaningful ways. This result suggests that policies affecting corporate cash distribution requirements have asset pricing implications through their impact on firms' production decisions and risk exposures. Our evidence that TDP predicts returns even among the largest firms indicates that these frictions affect a substantial portion of the economy's productive capacity.

2 Data

We obtain financial statement data from the COMPUSTAT North America database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data in COMPUSTAT, spanning several decades of annual observations. We focus on U.S.-incorporated firms trading on major exchanges and exclude financial firms (SIC codes 6000-6999) and utilities (SIC codes 4900-4999) following standard practice in the literature.signal construction relies on two key accounting variables from firms' annual financial statements. Income tax federal (TXFED) represents the federal income tax expense reported by the firm for the fiscal year, reflecting the company's tax obligations to the federal government based on its taxable income. Dividends common (DVC) captures the total cash dividends declared on common stock during the fiscal year, representing distributions to common shareholders. Both variables are measured in millions of dollars and reflect actual or declared amounts rather than estimates.construct the Tax Distribution Pressure signal by dividing federal income tax expense (TXFED) by common dividends (DVC) for each firm-year observation. This ratio captures the relative magnitude of a firm's tax obligations compared to its shareholder distributions, potentially indicating constraints on the firm's ability to maintain or increase dividend payments given its tax burden. We calculate this measure using fiscal year-end values from annual financial statements. To ensure data quality, we require non-missing and positive values for both TXFED and DVC, as negative or zero values in the denominator would result in undefined or economically meaningless ratios. We winsorize the resulting ratio at the 1st and 99th percentiles to mitigate the influence of extreme outliers.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the TDP signal. Panel A plots the time-series of the mean, median, and interquartile range for TDP. On average, the cross-sectional mean (median) TDP is 3.89 (0.95) over the 1967 to 2024 sample, where the starting date is determined by the availability of the input TDP data. The signal's interquartile range spans -0.00 to 3.72. Panel B of Figure 1 plots the time-series of the coverage of the TDP signal for the CRSP universe. On average, the TDP signal is available for 2.29% of CRSP names, which on average make up 5.31% of total market capitalization.

4 Does TDP predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on TDP using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high TDP portfolio and sells the low TDP portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short TDP strategy earns an average return of 0.36% per month with a t-statistic of 2.84. The annualized Sharpe ratio of the strategy is 0.37. The alphas range from 0.25% to 0.41% per month and have t-statistics exceeding 2.06 everywhere. The lowest alpha is with respect to the CAPM factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is -0.59, with a t-statistic of -8.02 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in $ millions) of the stocks they hold. In an average month, the five portfolios have at least 210 stocks and an average market capitalization of at least $826 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different protfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 20 bps/month with a t-statistics of 2.39. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-two exceed two, and for fifteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of Novy-Marx and Velikov (2016). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from Chen and Velikov (2022). The net average returns reported in the first column range between 9-46bps/month. The lowest return, (9 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 1.10. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the TDP trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in seventeen cases.

Table 3 provides direct tests for the role size plays in the TDP strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and TDP, as well as average returns and alphas for long/short trading TDP strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80^{th} NYSE percentile), the TDP strategy achieves an average return of 23 bps/month with a t-statistic of 1.76. Among these large cap stocks, the alphas for the TDP strategy relative to the five most common factor models range from 11 to 34 bps/month with t-statistics between 0.87 and 2.94.

5 How does TDP perform relative to the zoo?

Figure 2 puts the performance of TDP in context, showing the long/short strategy performance relative to other strategies in the "factor zoo." It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.[1] The vertical red line shows where the Sharpe ratio for the TDP strategy falls in the distribution. The TDP strategy's gross (net) Sharpe ratio of 0.37 (0.35) is greater than 80% (93%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a $1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a $1 invested in the TDP strategy (red line).[2] Ignoring trading costs, a $1 invested in the TDP strategy would have yielded $6.79 which ranks the TDP strategy in the top 2% across the 212 anomalies. Accounting for trading costs, a $1 invested in the TDP strategy would have yielded $5.46 which ranks the TDP strategy in the top 1% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the TDP relative to those. Panel A shows that the TDP strategy gross alphas fall between the 49 and 86 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196706 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The TDP strategy has a positive net generalized alpha for five out of the five factor models. In these cases TDP ranks between the 73 and 96 percentiles in terms of how much it could have expanded the achievable investment frontier.

[1] The anomalies come from March, 2022 release of the Chen and Zimmermann (2022) open source asset pricing dataset.

[2] The figure assumes an initial investment of $1 in T-bills and $1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

6 Does TDP add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of TDP with 201 filtered anomaly signals.[3] Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price TDP or at least to weaken the power TDP has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of TDP conditioning on each of the 201 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{TDP} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{TDP} TDP_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 201 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{TDP,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 201 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 201 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on TDP. Stocks are finally grouped into five TDP portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

[3] When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

TDP trading strategies conditioned on each of the 201 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on TDP and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the TDP signal in these Fama-MacBeth regressions exceed 0.58, with the minimum t-statistic occurring when controlling for gross profits / total assets. Controlling for all six closely related anomalies, the t-statistic on TDP is 2.12.

Similarly, Table 5 reports results from spanning tests that regress returns to the TDP strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the TDP strategy earns alphas that range from 29-40bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.75, which is achieved when controlling for gross profits / total assets. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the TDP trading strategy achieves an alpha of 25bps/month with a t-statistic of 2.27.

7 Does TDP add relative to the whole zoo?

Finally, we can ask how much adding TDP to the entire factor zoo could improve investment performance. Figure 8 plots the growth of $1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 156 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 156 anomalies augmented with the TDP signal.[4] We consider one different methods for combining signals.

[4]We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which TDP is available.

Panel A shows results using "Average rank" as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, $1 investment in the 156-anomaly combination strategy grows to $2068.13, while $1 investment in the combination strategy that includes TDP grows to $2314.57.

8 Conclusion

This study provides compelling evidence that Tax Distribution Pressure (TDP) represents a robust and economically significant predictor of cross-sectional equity returns. Our comprehensive analysis, following the rigorous protocol of Novy-Marx and Velikov (2023), demonstrates that TDP-based trading strategies generate substantial risk-adjusted returns that persist even after accounting for well-established risk factors and related anomalies.

The key findings reveal that a value-weighted long/short strategy based on TDP delivers an annualized Sharpe ratio of 0.37 gross (0.35 net of transaction costs), indicating strong economic viability even after accounting for implementation frictions. More importantly, the strategy's alpha remains statistically and economically significant relative to the Fama-French five factors plus momentum, generating 39 basis points per month gross (33 bps net) with robust t-statistics exceeding 3.0. The persistence of a 25 basis point monthly alpha even after controlling for six closely related strategies—including growth measures, profitability metrics, and leverage indicators—suggests that TDP captures a distinct source of return predictability not subsumed by existing factors in the literature.

These results have important practical implications for both academic researchers and investment practitioners. For academics, TDP adds to our understanding of how tax-related frictions and institutional features affect asset prices, potentially offering insights into market inefficiencies arising from tax-motivated trading. For practitioners, the signal's robustness to transaction costs and its incremental predictive power over established factors suggest it could enhance portfolio construction and risk management frameworks.

However, several limitations warrant consideration. First, while our analysis accounts for transaction costs, real-world implementation may face additional frictions such as market impact and capacity constraints that could erode returns at scale. Second, the regulatory and tax environment evolves over time, potentially affecting the stability and persistence of the TDP signal. Third, our analysis focuses primarily on U.S. equities, and the generalizability to international markets remains unexplored.

Future research should investigate several promising avenues. First, examining the time-varying nature of TDP's predictive power could reveal whether its effectiveness depends on market conditions, tax regime changes, or investor sentiment. Second, exploring the economic mechanisms underlying TDP's return predictability would enhance our theoretical understanding of this anomaly. Third, extending the analysis to international markets could test whether tax-related trading pressures generate similar return patterns across different institutional settings. Finally, investigating potential interactions between TDP and other tax-related phenomena, such as tax-loss selling or dividend tax effects, could provide a more comprehensive understanding of how taxation influences asset prices. Such research would not only advance our theoretical understanding of market efficiency but also inform more sophisticated investment strategies that account for the complex interplay between taxation and asset pricing.

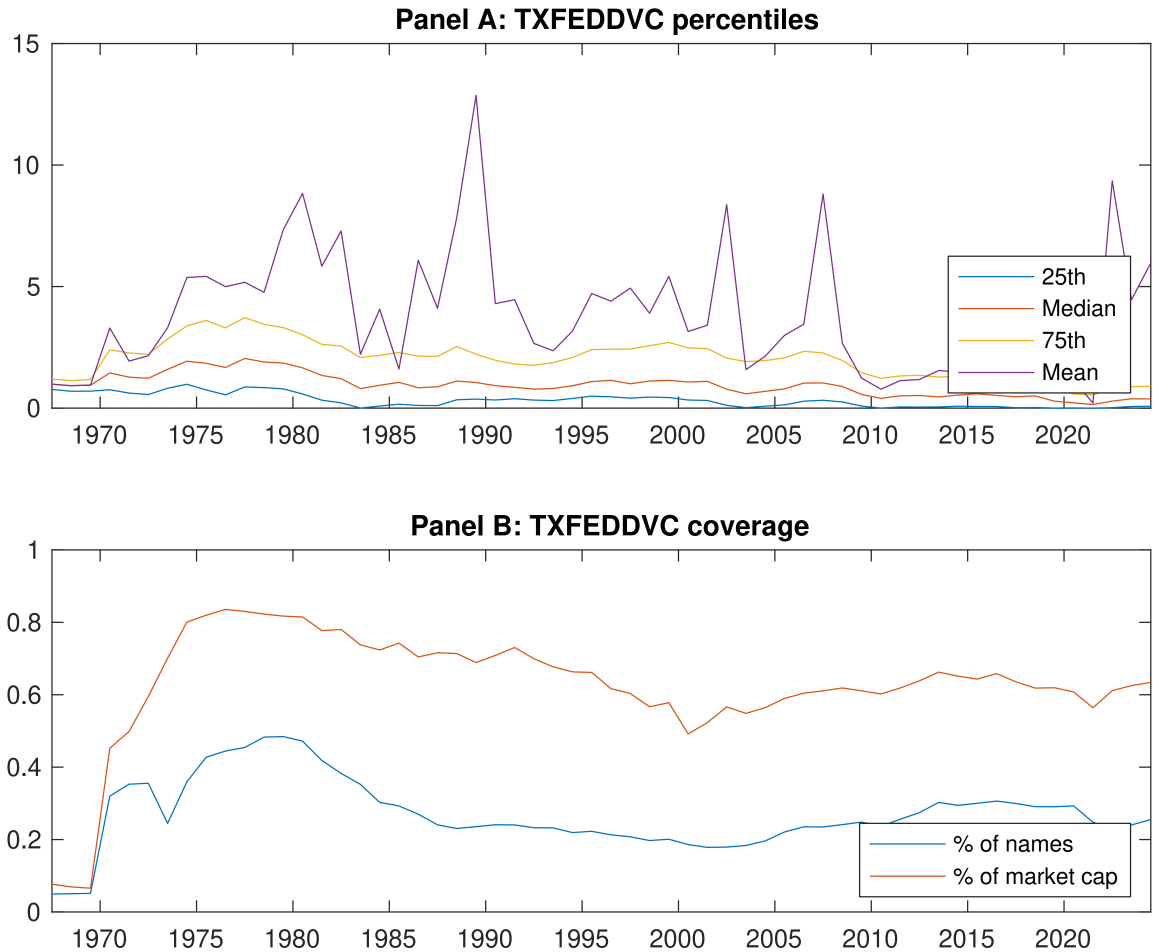

Figure 1: Times series of TDP percentiles and coverage.
This figure plots descriptive statistics for TDP. Panel A shows cross-sectional percentiles of TDP over the sample. Panel B plots the monthly coverage of TDP relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on TDP. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196706 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the TDP strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196706 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and TDP

This table presents results for conditional double sorts on size and TDP. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on TDP. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high TDP and short stocks with low TDP .Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196706 to 202406.

Panel A: portfolio average returns and time-series regression results

		TDP Quintiles					TDP Strategies					
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

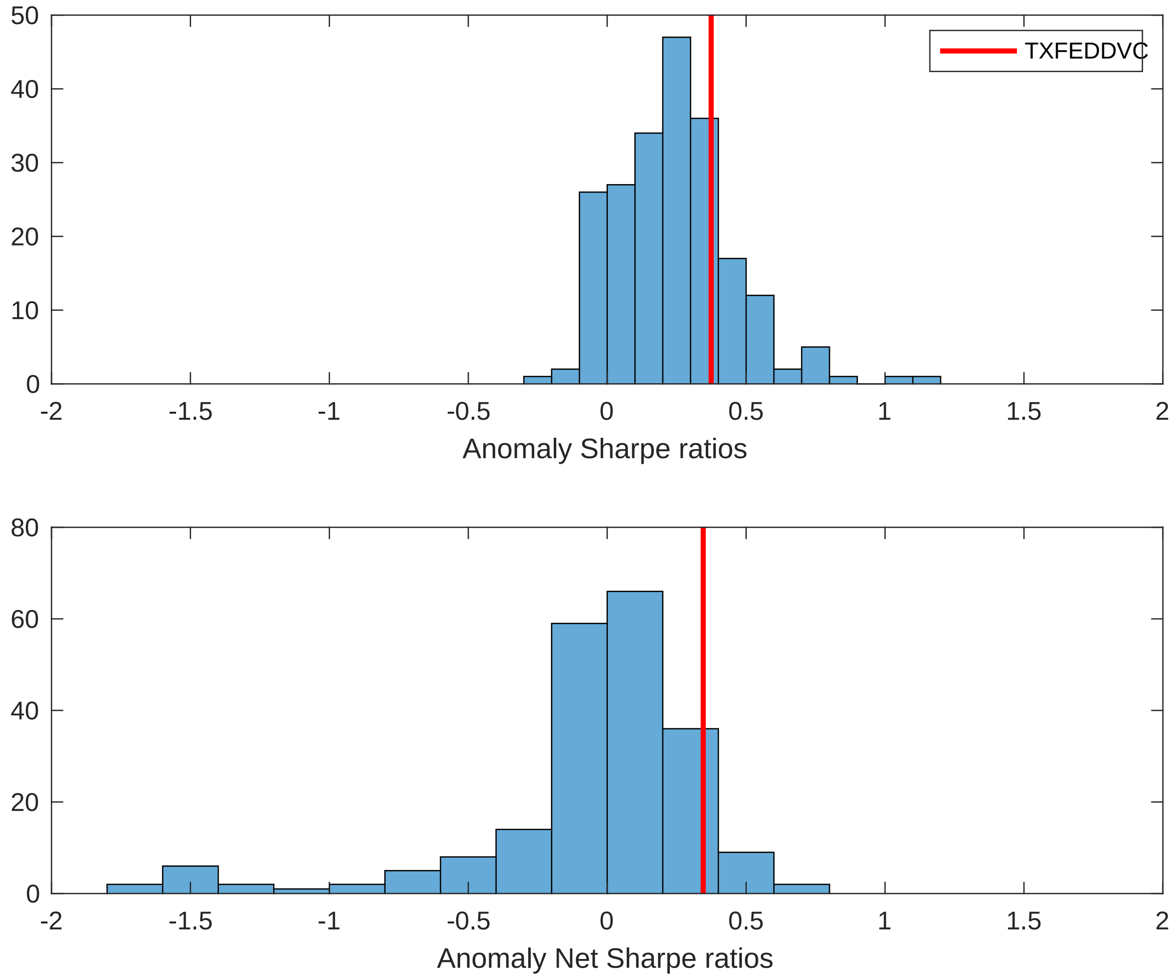

Figure 2: Distribution of Sharpe ratios.
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the TDP with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

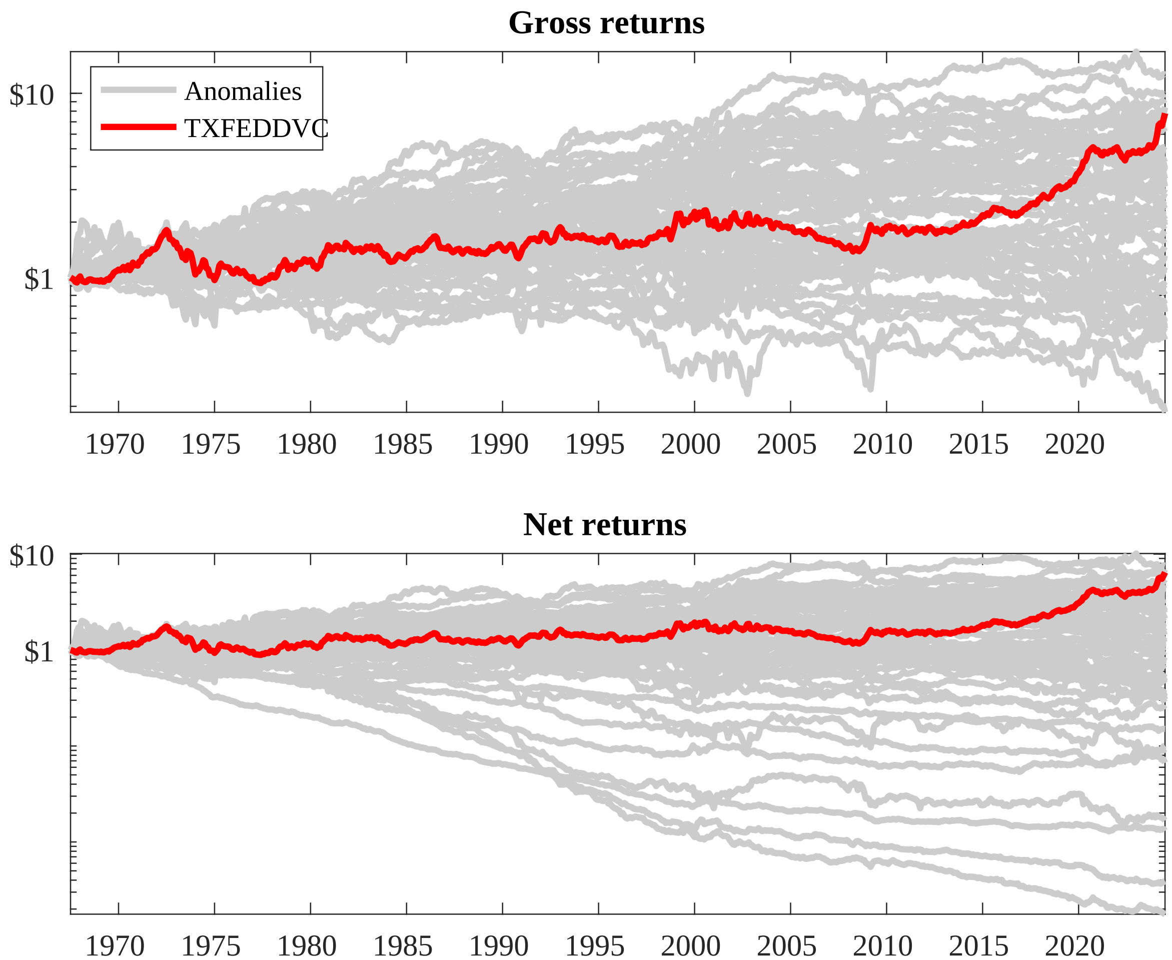

Figure 3: Dollar invested.
This figure plots the growth of a $1 invested in 212 anomaly trading strategies (gray lines), and compares those with the TDP trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strtaegy returns.

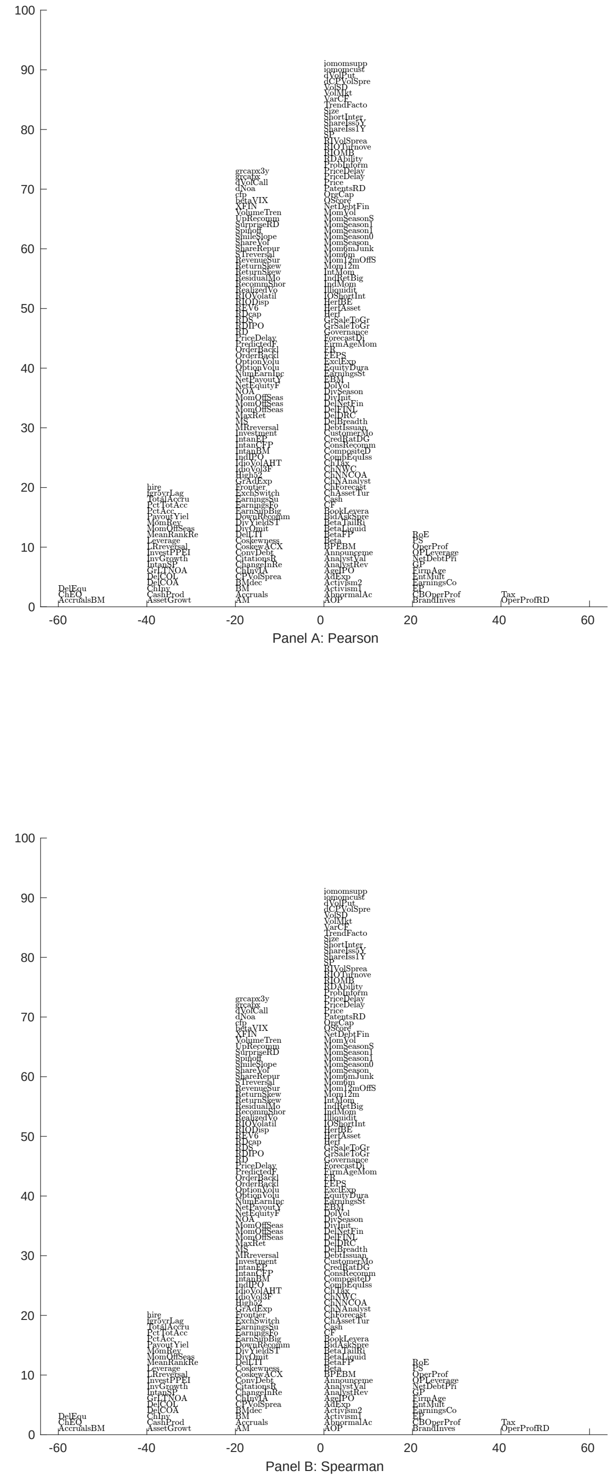

Figure 5: Distribution of correlations.
This figure plots a name histogram of correlations of 201 filtered anomaly signals with TDP. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

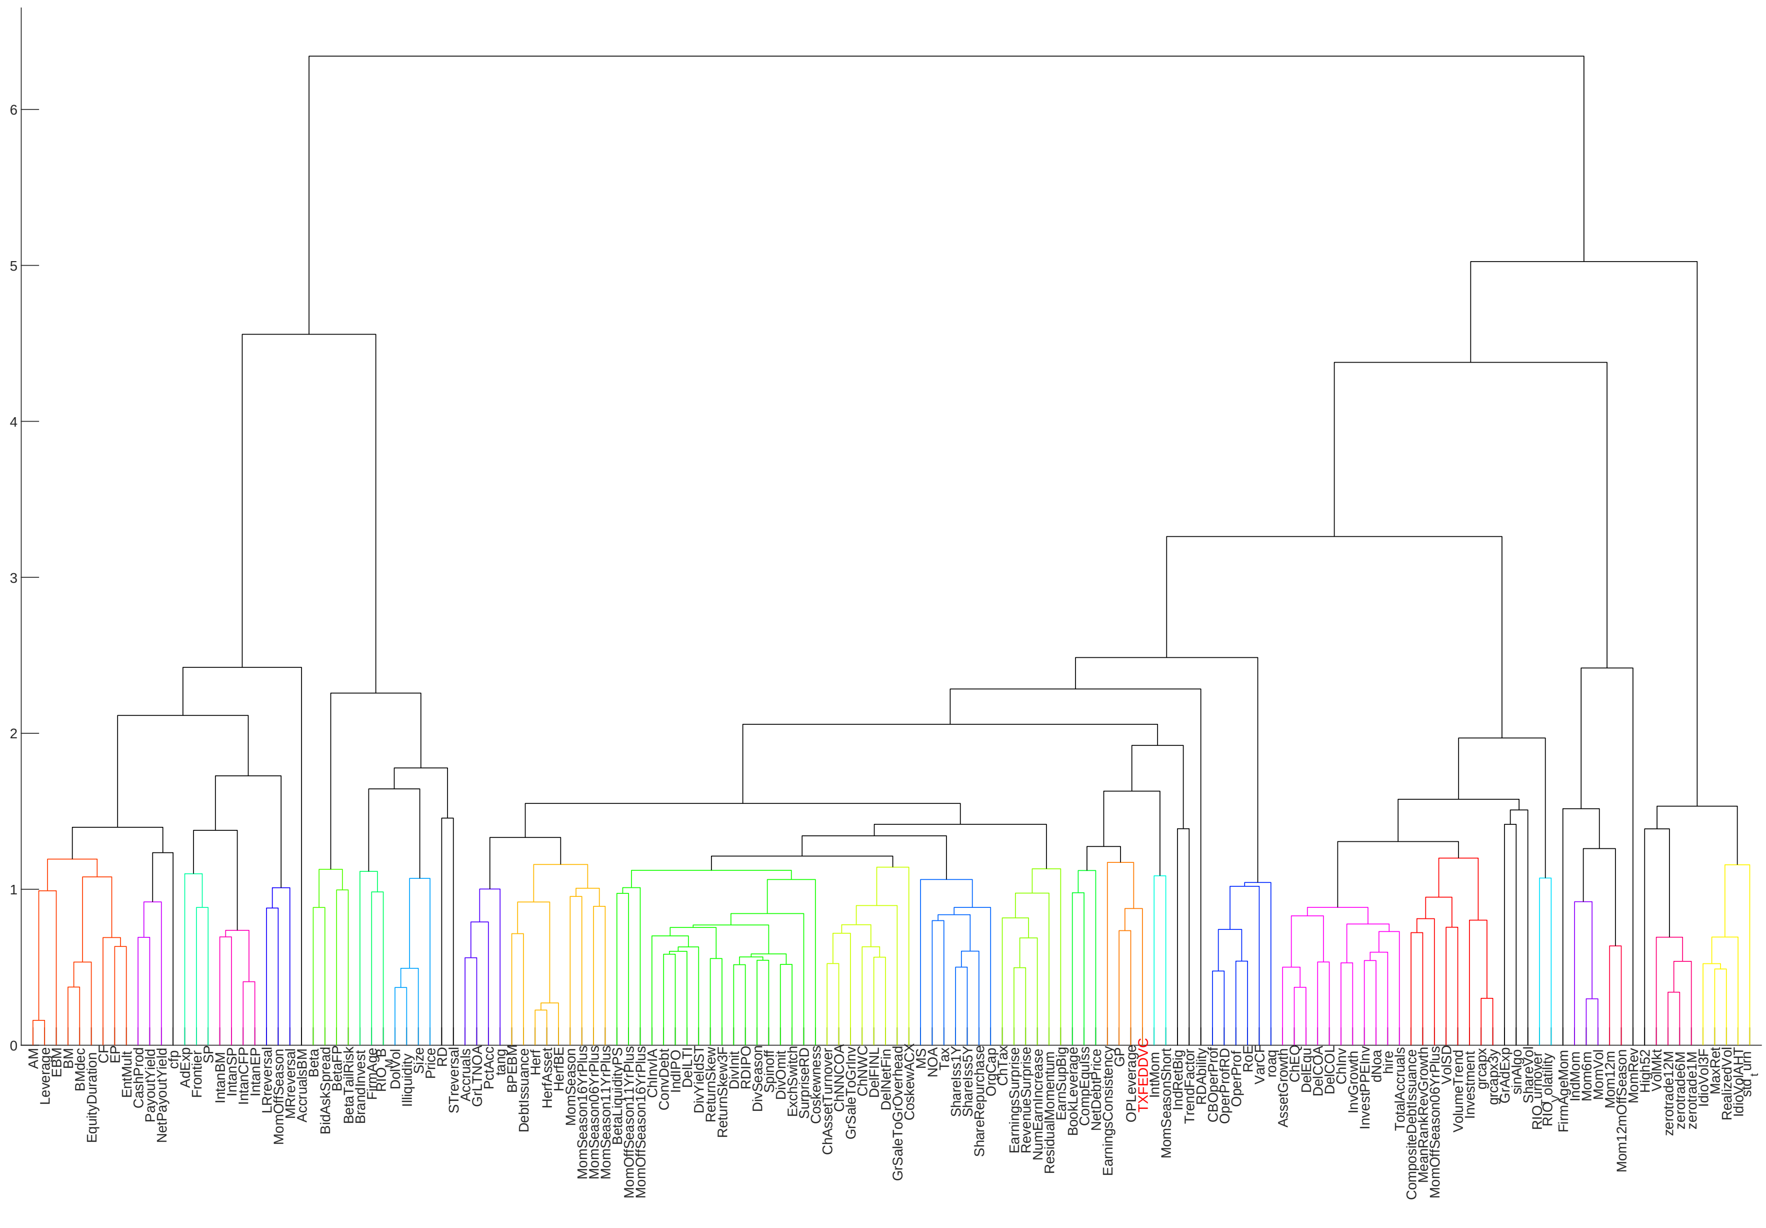

Figure 6: Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

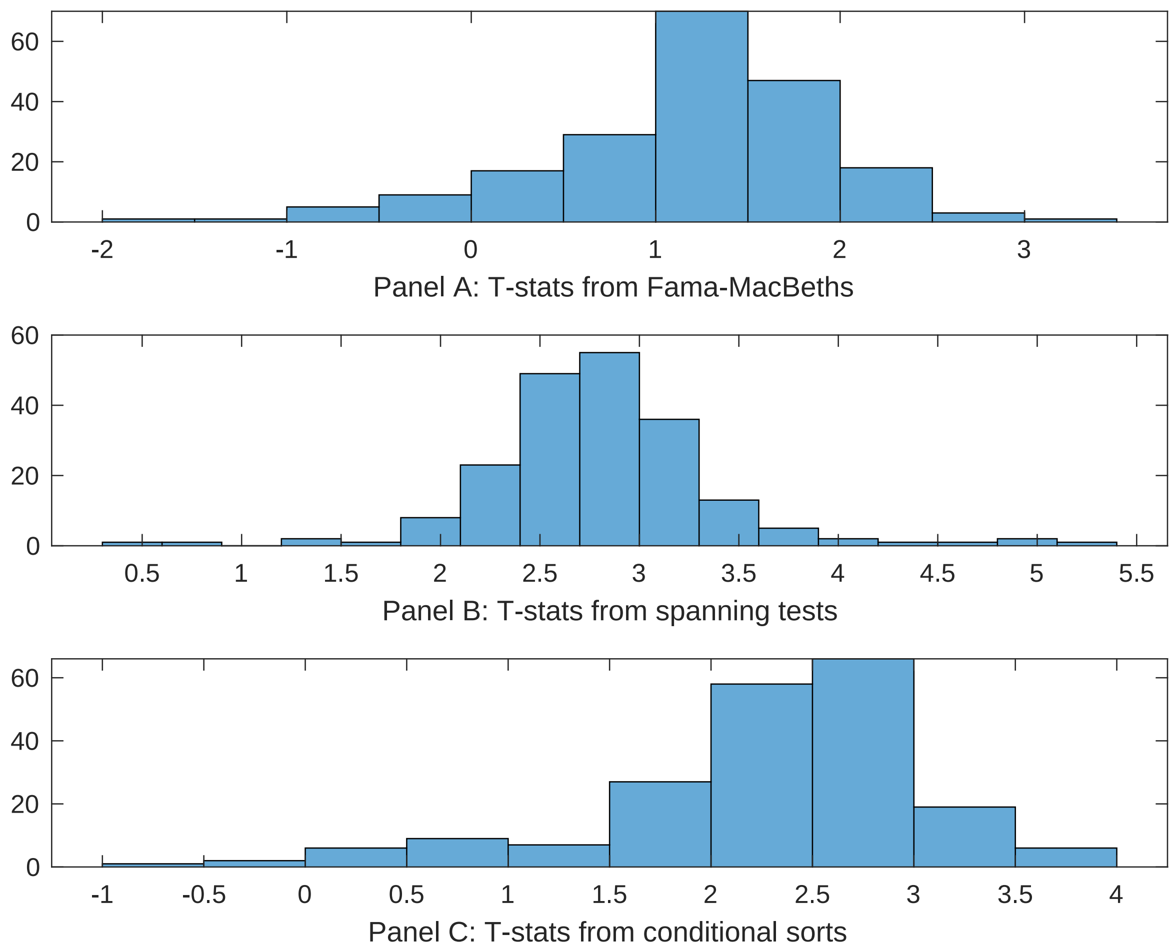

Figure 7: Distribution of t-stats on conditioning strategies
This figure plots histograms of t-statistics for predictability tests of TDP conditioning on each of the 201 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{TDP} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{TDP} TDP_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 201 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{TDP,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 201 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 201 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on TDP. Stocks are finally grouped into five TDP portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted TDP trading strategies conditioned on each of the 201 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies
This table presents Fama-MacBeth results of returns on TDP. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{TDP} TDP_{i,t} + \sum_{k=1}^{s} ix\beta_{X_k} X_{i,t}^{k} + \epsilon_{i,t}$. The six most closely related anomalies, X, are Growth in book equity, gross profits / total assets, Long-term EPS forecast, Change in equity to assets, Operating leverage, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196706 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the TDP trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{TDP} = \alpha + \sum_{k=1}^{6} \beta_{X_k} r_t^{X_k} + \sum_{j=1}^{6} \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor. The six most closely related anomalies, X, are Growth in book equity, gross profits / total assets, Long-term EPS forecast, Change in equity to assets, Operating leverage, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196706 to 202406.

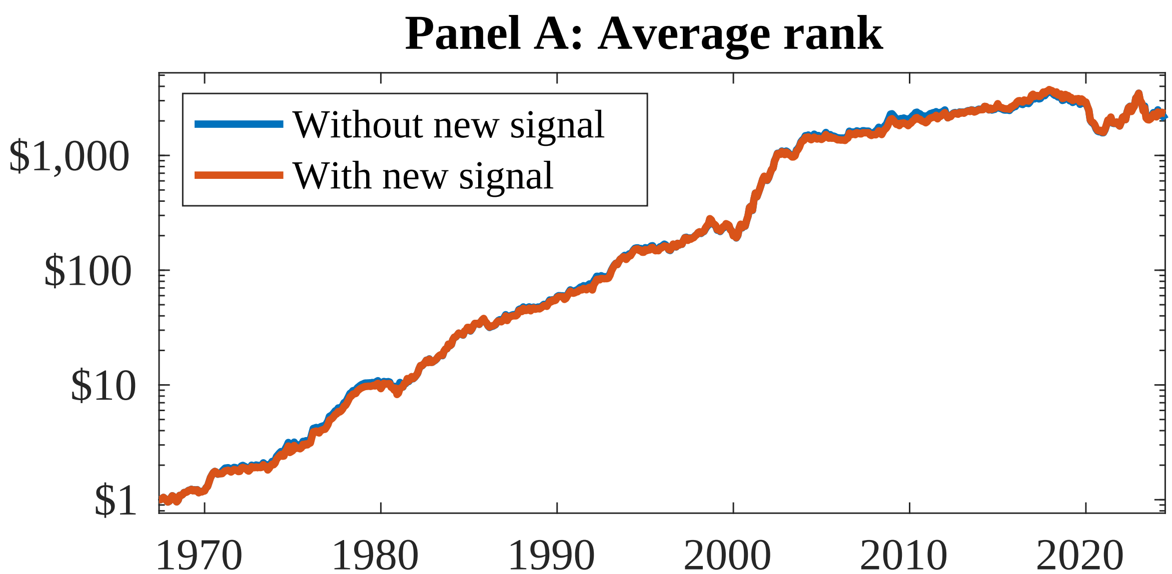

Figure 8: Combination strategy performance
This figure plots the growth of a $1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). In all panels, the blue solid lines indicate combination trading strategies that utilize 156 anomalies. The red solid lines indicate combination trading strategies that utilize the 156 anomalies as well as TDP. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
