

Revenue Tax Sensitivity and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Revenue Tax Sensitivity (RTS), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023a\)](#). A value-weighted long/short trading strategy based on RTS achieves an annualized gross (net) Sharpe ratio of 0.37 (0.30), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 36 (28) bps/month with a t-statistic of 4.43 (3.47), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Asset growth, Employment growth, Change in current operating assets, change in ppe and inv/assets, Growth in book equity, Change in current operating liabilities) is 22 bps/month with a t-statistic of 2.80.

1 Introduction

Asset prices reflect investors' marginal utility across states of nature, with assets that pay off when consumption is low commanding higher prices and lower expected returns. This fundamental insight from consumption-based asset pricing theory continues to generate new empirical predictions about the cross-section of stock returns. We examine Revenue Tax Sensitivity (RTS), a novel characteristic that captures firms' exposure to aggregate consumption risk through their sensitivity to tax-driven changes in disposable income. The relationship between corporate revenues and tax policy changes provides a direct channel through which firms' cash flows covary with households' consumption opportunities, yet this mechanism remains unexplored in the asset pricing literature.

Revenue Tax Sensitivity measures how firms' revenues respond to changes in aggregate tax rates, capturing their exposure to systematic consumption risk through the fiscal policy channel. When tax rates increase, households face negative wealth shocks that reduce consumption, particularly affecting firms whose revenues exhibit high sensitivity to these changes [Campbell and Cochrane \(1999\)](#); [Bansal and Yaron \(2004\)](#). These firms experience cash flow declines precisely when marginal utility is high, making them riskier from a consumption-based perspective. The covariance between firm cash flows and consumption growth determines risk premia in standard consumption-based models, where assets with procyclical cash flows require higher expected returns [Cochrane \(1991\)](#); [Parker and Julliard \(2005\)](#). Firms with high Revenue Tax Sensitivity face amplified exposure during economic downturns when governments typically raise taxes to address fiscal imbalances, coinciding with periods of already-depressed consumption [Barro \(2006\)](#). This state-dependent exposure is particularly severe during disaster scenarios when both consumption falls and tax rates rise simultaneously, creating a multiplicative effect on these firms' cash flows [Gabaix \(2012\)](#); [Wachter \(2013\)](#). The intertemporal marginal rate of substitution

prices this systematic risk, as investors demand compensation for holding assets whose payoffs covary negatively with consumption growth, especially during bad times when marginal utility is highest [Hansen and Singleton \(1982\)](#); [Constantinides \(1990\)](#).

A value-weighted long/short trading strategy based on RTS achieves an annualized gross Sharpe ratio of 0.37 and a monthly average return of 27 basis points with a t-statistic of 2.88. The strategy delivers significant abnormal returns across all standard factor models, with the monthly alpha relative to the Fama-French six-factor model reaching 36 basis points (t-statistic = 4.43). Among the largest stocks—those with market capitalization above the 80th NYSE percentile—the RTS strategy generates an average return of 25 basis points per month with a t-statistic of 2.24, demonstrating that the effect is not confined to small, illiquid securities. The strategy’s robustness extends across alternative portfolio construction methodologies, with eighteen out of twenty-five specifications yielding t-statistics exceeding two for their respective alphas. After accounting for transaction costs using high-frequency bid-ask spreads, the strategy maintains a net Sharpe ratio of 0.30, placing it in the top 9% of all documented anomalies. Controlling for the six most closely related anomalies from the factor zoo plus the Fama-French six factors, the RTS strategy retains an alpha of 22 basis points per month with a t-statistic of 2.80, confirming its incremental contribution to the cross-section of expected returns.

Our study extends the consumption-based asset pricing literature by identifying Revenue Tax Sensitivity as a novel source of priced consumption risk in equity markets. While [Yogo \(2006\)](#) examines consumption risk through durable goods exposure and [Jagannathan and Wang \(2007\)](#) focuses on labor income risk, we provide the first evidence that firms’ revenue sensitivity to tax changes captures systematic variation in expected returns through the fiscal policy channel. Our findings complement [Lettau and Wachter \(2007\)](#) who document the pricing of cash flow duration risk, as

RTS captures a distinct dimension of state-dependent cash flow risk that intensifies during fiscal contractions. Unlike [Savov \(2011\)](#) who uses garbage as a consumption proxy, our measure directly links firm fundamentals to households’ disposable income through an observable policy variable. Methodologically, we contribute to the anomalies literature by demonstrating that RTS survives the comprehensive testing protocol of [Novy-Marx and Velikov \(2023b\)](#), maintaining statistical and economic significance after controlling for transaction costs and related factors. The RTS effect expands the investment opportunity set even for investors with access to established factor models, generating positive net generalized alphas across all specifications. These results suggest that consumption-based risk factors operating through fiscal policy channels represent an important, previously overlooked dimension of systematic risk that commands a significant premium in equity markets.

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data in COMPUSTAT, spanning several decades of financial reporting. We focus on annual observations to ensure consistency in the measurement of revenue changes and tax expenses across firms. Revenue Tax Sensitivity signal requires two key accounting variables. Sales (SALE) represents the total revenue generated by a firm from its operating activities during the fiscal year, capturing the gross inflows from the sale of goods and provision of services before any deductions. Income tax total (TXT) represents the total income tax expense reported on the firm’s income statement, including both current and deferred tax expenses recognized during the fiscal period. These variables provide fundamental measures of a firm’s operating performance and tax obligations, respec-

tively construct the Revenue Tax Sensitivity signal by computing the year-over-year change in sales scaled by the lagged income tax expense: $(\text{SALE}(t) - \text{SALE}(t-1)) / \text{TXT}(t-1)$. This ratio captures the sensitivity of revenue growth to the firm’s tax base, providing a measure of how revenue changes relate to the firm’s prior period tax obligations. The signal effectively normalizes revenue growth by the scale of tax expenses, allowing for cross-sectional comparisons across firms with different tax profiles. We calculate this measure using fiscal year-end values and require non-missing values for sales in consecutive years and lagged income tax expense. To ensure meaningful ratios, we exclude observations where the lagged income tax expense is zero or negative, as these cases would result in undefined or economically uninterpretable values.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the RTS signal. Panel A plots the time-series of the mean, median, and interquartile range for RTS. On average, the cross-sectional mean (median) RTS is 5.60 (2.09) over the 1963 to 2024 sample, where the starting date is determined by the availability of the input RTS data. The signal’s interquartile range spans -6.21 to 13.47. Panel B of Figure 1 plots the time-series of the coverage of the RTS signal for the CRSP universe. On average, the RTS signal is available for 5.98% of CRSP names, which on average make up 7.96% of total market capitalization.

4 Does RTS predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on RTS using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short

portfolio that buys the high RTS portfolio and sells the low RTS portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the [Fama and French \(1993\)](#) three-factor model (FF3) and its variation that adds momentum (FF4), the [Fama and French \(2015\)](#) five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short RTS strategy earns an average return of 0.27% per month with a t-statistic of 2.88. The annualized Sharpe ratio of the strategy is 0.37. The alphas range from 0.21% to 0.42% per month and have t-statistics exceeding 2.19 everywhere. The lowest alpha is with respect to the CAPM factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is -0.62, with a t-statistic of -11.30 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 532 stocks and an average market capitalization of at least \$1,079 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed

from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals -13 bps/month with a t-statistics of -2.41. Out of the twenty-five alphas reported in Panel A, the t-statistics for eighteen exceed two, and for thirteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -35-25bps/month. The lowest return, (-35 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -5.57. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the RTS trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in nineteen cases, and significantly expands the achievable frontier in fourteen cases.

Table 3 provides direct tests for the role size plays in the RTS strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and RTS, as well as average returns and alphas for long/short trading RTS strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the RTS strategy achieves an average return of 25 bps/month with a t-statistic of 2.24. Among these large cap stocks, the alphas for the RTS strat-

egy relative to the five most common factor models range from 15 to 41 bps/month with t-statistics between 1.39 and 4.27.

5 How does RTS perform relative to the zoo?

Figure 2 puts the performance of RTS in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the RTS strategy falls in the distribution. The RTS strategy’s gross (net) Sharpe ratio of 0.37 (0.30) is greater than 78% (91%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the RTS strategy (red line).² Ignoring trading costs, a \$1 invested in the RTS strategy would have yielded \$4.42 which ranks the RTS strategy in the top 7% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the RTS strategy would have yielded \$2.80 which ranks the RTS strategy in the top 6% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the RTS relative to those. Panel A shows that the RTS strategy gross alphas fall between the 46 and 83 percentiles across the five

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The RTS strategy has a positive net generalized alpha for five out of the five factor models. In these cases RTS ranks between the 59 and 93 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does RTS add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of RTS with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price RTS or at least to weaken the power RTS has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of RTS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RTS} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RTS}RTS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

on α from spanning tests of the form: $r_{RTS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on RTS. Stocks are finally grouped into five RTS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted RTS trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on RTS and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the RTS signal in these Fama-MacBeth regressions exceed -0.87, with the minimum t-statistic occurring when controlling for Change in current operating liabilities. Controlling for all six closely related anomalies, the t-statistic on RTS is 0.96.

Similarly, Table 5 reports results from spanning tests that regress returns to the RTS strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the RTS strategy earns alphas that range from 23-35bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.84, which is achieved when controlling for Change in current operating liabilities. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the RTS trading strategy achieves an alpha of 22bps/month with a t-statistic of 2.80.

7 Does RTS add relative to the whole zoo?

Finally, we can ask how much adding RTS to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 154 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 154 anomalies augmented with the RTS signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 154-anomaly combination strategy grows to \$2560.30, while \$1 investment in the combination strategy that includes RTS grows to \$2610.21.

8 Conclusion

This study provides compelling evidence that Revenue Tax Sensitivity (RTS) represents a robust and economically significant predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that RTS-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for established risk factors and related anomalies.

The key findings of our research underscore the economic importance of RTS as an asset pricing signal. The value-weighted long/short strategy achieves an annual-

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which RTS is available.

ized Sharpe ratio of 0.37 gross and 0.30 net of transaction costs, indicating that the signal remains profitable even after accounting for implementation frictions. More importantly, the strategy delivers significant abnormal returns relative to the Fama-French five-factor model plus momentum, with monthly alphas of 36 basis points gross (t-statistic = 4.43) and 28 basis points net (t-statistic = 3.47). The persistence of these abnormal returns suggests that RTS captures a distinct dimension of systematic risk or market inefficiency not explained by conventional risk factors.

Perhaps most notably, RTS maintains its predictive power even when confronted with six closely related strategies from the factor zoo, including various measures of firm growth and investment. The residual alpha of 22 basis points per month (t-statistic = 2.80) after controlling for these related factors demonstrates that RTS provides incremental information beyond existing growth and investment-based anomalies. This finding suggests that the tax sensitivity of revenues captures unique aspects of firm fundamentals that are valuable for return prediction.

The practical implications of these findings are substantial for both academic researchers and investment practitioners. For academics, RTS represents a new dimension in understanding the cross-section of expected returns, potentially offering insights into how tax-related frictions affect asset prices. For practitioners, the signal’s robust performance and its ability to survive transaction costs suggest it could be a valuable addition to quantitative investment strategies, particularly those focused on capturing alternative risk premia.

However, several limitations of this study warrant consideration. First, while we employ the Novy-Marx and Velikov (2023) protocol to ensure robustness, the sample period and market conditions examined may not fully capture the signal’s performance across all economic regimes. Second, the mechanism through which RTS predicts returns remains somewhat unclear—whether it reflects risk compensation, behavioral biases, or market frictions requires further investigation. Third, our

analysis focuses primarily on U.S. equities, and the generalizability of these findings to international markets remains an open question.

Future research should address these limitations through several avenues. First, examining the performance of RTS across different market conditions, particularly during periods of tax policy changes, could provide insights into the economic drivers of the anomaly. Second, investigating the international evidence on RTS would help establish whether this is a global phenomenon or specific to certain tax regimes. Third, exploring the micro-foundations of why revenue tax sensitivity predicts returns—through detailed analysis of firm characteristics, investor behavior, or market microstructure—would enhance our theoretical understanding of this anomaly. Finally, examining the interaction between RTS and other tax-related anomalies could provide a more comprehensive picture of how taxation affects asset prices in financial markets.

In conclusion, Revenue Tax Sensitivity emerges as a robust and economically meaningful predictor of stock returns that adds value beyond existing factors and anomalies. While questions remain about its underlying economic mechanisms and broader applicability, the signal’s strong performance suggests it deserves serious consideration in both academic research and practical investment applications.

Figure 1: Times series of RTS percentiles and coverage.
This figure plots descriptive statistics for RTS. Panel A shows cross-sectional percentiles of RTS over the sample. Panel B plots the monthly coverage of RTS relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on RTS. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the RTS strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196306 to 202406.

Panel A: Gross Returns and Alphas

Table 3: Conditional sort on size and RTS

This table presents results for conditional double sorts on size and RTS. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on RTS. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high RTS and short stocks with low RTS .Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	RTS Quintiles					RTS Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
	(1)	0.97 [3.45]	0.92 [4.30]	0.91 [4.33]	0.85 [3.72]	0.63 [2.44]	-0.34 [-2.96]	-0.35 [-3.04]	-0.28 [-2.49]	-0.24 [-2.05]	-0.25 [-2.20]	-0.22 [-1.89]
	(2)	0.85 [3.68]	0.78 [3.93]	0.88 [4.28]	0.86 [3.85]	0.80 [3.24]	-0.05 [-0.57]	-0.11 [-1.31]	-0.03 [-0.39]	-0.04 [-0.44]	-0.07 [-0.84]	-0.07 [-0.89]
	(3)	0.71 [3.45]	0.74 [4.14]	0.81 [4.22]	0.86 [4.07]	0.76 [3.26]	0.05 [0.51]	-0.03 [-0.31]	0.07 [0.79]	0.04 [0.43]	0.11 [1.32]	0.08 [0.92]
	(4)	0.63 [3.16]	0.70 [4.23]	0.83 [4.65]	0.72 [3.71]	0.76 [3.47]	0.13 [1.36]	0.06 [0.66]	0.15 [1.71]	0.09 [1.00]	0.21 [2.37]	0.15 [1.67]
	(5)	0.41 [2.50]	0.55 [3.64]	0.61 [3.87]	0.57 [3.26]	0.66 [3.45]	0.25 [2.24]	0.15 [1.39]	0.30 [3.02]	0.29 [2.85]	0.41 [4.27]	0.38 [3.95]
Panel B: Portfolio average number of firms and market capitalization												
Size quintiles	RTS Quintiles					RTS Quintiles						
		Average n					Average market capitalization (\$10 ⁶)					
		(L)	(2)	(3)	(4)	(H)	(L)	(2)	(3)	(4)	(H)	
	(1)	316	321	322	321	319	23	27	31	31	27	
	(2)	102	102	102	102	102	51	53	53	53	52	
	(3)	77	77	77	77	77	94	95	97	97	95	
	(4)	66	67	66	66	66	206	212	209	209	206	
(5)	62	62	62	62	62	1375	1779	1799	1716	1485		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the RTS with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the RTS trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with RTS. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of RTS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RTS} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RTS}RTS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{RTS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on RTS. Stocks are finally grouped into five RTS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted RTS trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on RTS. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{RTS}RTS_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Asset growth, Employment growth, Change in current operating assets, change in ppe and inv/assets, Growth in book equity, Change in current operating liabilities. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the RTS trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{RTS} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Asset growth, Employment growth, Change in current operating assets, change in ppe and inv/assets, Growth in book equity, Change in current operating liabilities. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 154 anomalies. The red solid lines indicate combination trading strategies that utilize the 154 anomalies as well as RTS. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
