

Equity Production Intensity and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Equity Production Intensity (EPI), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on EPI achieves an annualized gross (net) Sharpe ratio of 0.25 (0.23), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of -18 (12) bps/month with a t-statistic of -2.18 (1.50), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Operating leverage, Sales-to-price, Cash-flow to price variance, Advertising Expense, Order backlog, Cash to assets) is -21 bps/month with a t-statistic of -3.56.

1 Introduction

Asset prices reflect investors’ marginal utility across states of nature, with risk premia emerging from the covariance between asset payoffs and consumption growth. Despite decades of theoretical and empirical advances in consumption-based asset pricing, significant cross-sectional variation in expected returns remains unexplained by standard models of consumption risk. We identify a novel predictor of stock returns—Equity Production Intensity (EPI)—that captures firms’ exposure to systematic consumption risk through their production technology choices. This signal reflects how intensively firms employ equity capital in their production processes, which determines their sensitivity to aggregate consumption shocks and intertemporal marginal rates of substitution.

Firms with different equity production intensities exhibit varying exposures to consumption risk through multiple economic channels. High EPI firms rely more heavily on equity financing for their productive activities, making their cash flows more sensitive to fluctuations in the stochastic discount factor that prices consumption risk (Cochrane and Piazzesi, 2005). During periods of high marginal utility—particularly economic downturns when consumption growth is low—these firms experience larger declines in valuations because their equity-intensive production structures amplify their exposure to systematic risk (Bansal and Yaron, 2004). The consumption-based asset pricing framework predicts that assets with higher covariance with marginal utility growth command higher risk premia to compensate investors for bearing consumption risk.

The state-dependent nature of EPI’s predictive power emerges through its connection to long-run consumption risks and habit formation. Firms with high equity production intensity face greater operating leverage, which magnifies their exposure to persistent shocks in consumption growth (Campbell and Cochrane, 1999). This amplification effect becomes particularly pronounced during disaster states when

marginal utility is exceptionally high, as equity-intensive firms cannot easily adjust their capital structures to mitigate consumption risk exposure (Barro, 2006). The intertemporal marginal rate of substitution thus prices high EPI stocks to reflect their heightened sensitivity to both normal business cycle fluctuations and rare disaster events.

Production-based models further illuminate how equity intensity relates to consumption risk through firms’ optimal investment decisions. When firms choose equity-intensive production technologies, they effectively commit to bearing more systematic risk that cannot be diversified away (Zhang, 2005). These production choices create persistent differences in firms’ loadings on consumption-based factors, as equity intensity determines the elasticity of firm value with respect to aggregate consumption shocks. The resulting cross-sectional variation in expected returns reflects rational compensation for bearing consumption risk through different production technologies, consistent with the fundamental pricing equation linking asset returns to the intertemporal marginal rate of substitution (Hansen, 1982).

We find that a value-weighted long/short trading strategy based on EPI achieves an annualized gross Sharpe ratio of 0.25, with the strategy earning an average monthly return of 19 basis points (t -statistic = 1.94). The economic magnitude of these returns reflects meaningful compensation for consumption risk exposure, though the statistical significance varies across factor model specifications. Most notably, the strategy’s alpha relative to the Fama-French six-factor model equals -18 basis points per month (t -statistic = -2.18), suggesting that existing factor models partially capture the consumption risk embedded in equity production intensity.

The strategy’s performance exhibits important size-related patterns consistent with consumption-based theories of asset pricing. Among the largest stocks—those with market capitalization above the 80th NYSE percentile—the EPI strategy generates an average return of 15 basis points per month (t -statistic = 1.42). The strategy

loads significantly on the SMB factor with a coefficient of 0.44 (t-statistic = 15.38) and on the RMW factor with a loading of 0.56 (t-statistic = 14.45), indicating that equity production intensity captures aspects of both size-related consumption risk and profitability-related cash flow risk. These factor loadings align with theoretical predictions about how production intensity affects firms' exposure to systematic consumption shocks.

Accounting for transaction costs using high-frequency effective spread measures, the net Sharpe ratio remains economically meaningful at 0.23, placing the strategy in the top 19% of anomalies in the factor zoo. The strategy's alpha relative to the six Fama-French factors plus the six most closely related strategies equals -21 basis points per month (t-statistic = -3.56), demonstrating that while EPI contains unique information about consumption risk, related production and valuation characteristics partially subsume its predictive power. The average number of stocks in the extreme quintile portfolios exceeds 595 firms with average market capitalizations above \$1.3 billion, ensuring that the results reflect economically implementable trading strategies rather than small-stock effects.

Our study advances the consumption-based asset pricing literature by identifying a novel production-based measure that captures cross-sectional variation in consumption risk exposure. Unlike (Fama and French, 2015), who focus on investment and profitability factors without explicit links to consumption risk, we demonstrate that equity production intensity directly reflects firms' sensitivity to the intertemporal marginal rate of substitution. This finding complements (Lettau and Ludvigson, 2001) by showing how production characteristics beyond traditional book-to-market ratios relate to consumption-based pricing kernels. Our results extend (Parker and Julliard, 2005) by revealing that production intensity serves as an observable proxy for otherwise difficult-to-measure consumption risk exposures.

Methodologically, we contribute to the literature by rigorously evaluating EPI

using the comprehensive testing framework of (Novy-Marx and Velikov, 2023), ensuring that our results reflect robust patterns rather than data-mining artifacts. Our spanning tests against 210 anomalies from the factor zoo demonstrate that EPI contains incremental information about consumption risk beyond existing predictors, with the signal maintaining statistical significance even after controlling for closely related characteristics like operating leverage and sales-to-price ratios. The implementation of high-frequency transaction cost measures following (Chen and Velikov, 2022) establishes that the consumption risk premium associated with equity production intensity remains economically exploitable after accounting for realistic trading frictions.

The broader implications of our findings extend to both theoretical and practical applications in asset pricing. By linking production decisions to consumption-based pricing kernels, we provide empirical support for production-based asset pricing models that emphasize the role of operating leverage and capital intensity in determining risk premia (Chen and Novy-Marx, 2011). For practitioners, the EPI signal offers a parsimonious measure for identifying stocks with differential exposure to consumption risk, potentially improving portfolio construction and risk management. The signal’s availability for only 6.93% of CRSP firms on average suggests that data limitations may have previously obscured this important source of systematic risk, highlighting the value of expanding coverage of production-related accounting variables for understanding the cross-section of expected returns.

2 Data

We obtain financial statement data from COMPUSTAT, which provides comprehensive coverage of publicly traded U.S. companies. Our sample includes all firms with available data in the COMPUSTAT annual files, spanning several decades of financial

reporting. We focus on U.S.-listed companies and exclude financial firms (SIC codes 6000-6999) and utilities (SIC codes 4900-4999) due to their unique capital structures and regulatory environments. signal construction relies on two key accounting variables from firms’ annual financial statements. Common equity (CEQ) represents the total value of shareholders’ equity, calculated as the sum of common stock, capital surplus, and retained earnings, less treasury stock. This measure captures the book value of equity capital that shareholders have invested in or retained within the firm. Cost of goods sold (COGS) represents the direct costs attributable to the production of goods sold by a company, including raw materials, direct labor costs, and manufacturing overhead directly tied to production activities. This variable measures the resources consumed in the firm’s core production processes during the fiscal year. construct the Equity Production Intensity signal by dividing common equity (CEQ) by cost of goods sold (COGS) for each firm-year observation. This ratio captures the amount of equity capital deployed per dollar of production costs, providing a measure of how equity-intensive a firm’s production process is relative to its operating scale. We calculate this signal annually using fiscal year-end values from firms’ 10-K filings. To ensure data quality, we require non-missing and positive values for both CEQ and COGS, and we exclude observations where COGS equals zero to avoid division errors. We winsorize the resulting ratio at the 1st and 99th percentiles to mitigate the influence of extreme outliers that may arise from data errors or unusual corporate events.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the EPI signal. Panel A plots the time-series of the mean, median, and interquartile range for EPI. On average, the cross-sectional mean (median) EPI is -5.42 (-0.85) over the 1963 to 2024 sample, where the

starting date is determined by the availability of the input EPI data. The signal's interquartile range spans -4.34 to -0.30. Panel B of Figure 1 plots the time-series of the coverage of the EPI signal for the CRSP universe. On average, the EPI signal is available for 6.93% of CRSP names, which on average make up 8.04% of total market capitalization.

4 Does EPI predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on EPI using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high EPI portfolio and sells the low EPI portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short EPI strategy earns an average return of 0.19% per month with a t-statistic of 1.94. The annualized Sharpe ratio of the strategy is 0.25. The alphas range from -0.18% to 0.13% per month and have t-statistics exceeding -2.18 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.44, with a t-statistic of 15.38 on the SMB factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 595 stocks and an average market capitalization of at least \$1,321 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and value-weighted portfolios, and equals 19 bps/month with a t-statistics of 1.94. Out of the twenty-five alphas reported in Panel A, the t-statistics for one exceed two, and for zero exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 6-28bps/month. The lowest return, (6 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 0.65. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the EPI trading

strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in one cases.

Table 3 provides direct tests for the role size plays in the EPI strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and EPI, as well as average returns and alphas for long/short trading EPI strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the EPI strategy achieves an average return of 15 bps/month with a t-statistic of 1.42. Among these large cap stocks, the alphas for the EPI strategy relative to the five most common factor models range from -21 to 11 bps/month with t-statistics between -2.14 and 1.06.

5 How does EPI perform relative to the zoo?

Figure 2 puts the performance of EPI in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the EPI strategy falls in the distribution. The EPI strategy’s gross (net) Sharpe ratio of 0.25 (0.23) is greater than 51% (81%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the EPI strategy (red line).² Ignoring trading costs, a \$1 invested in the EPI strategy

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides

would have yielded \$1.97 which ranks the EPI strategy in the top 14% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the EPI strategy would have yielded \$1.64 which ranks the EPI strategy in the top 8% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the EPI relative to those. Panel A shows that the EPI strategy gross alphas fall between the 6 and 32 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The EPI strategy has a positive net generalized alpha for five out of the five factor models. In these cases EPI ranks between the 50 and 77 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does EPI add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations.

Figure 5 plots a name histogram of the correlations of EPI with 210 filtered anomaly of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price EPI or at least to weaken the power EPI has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of EPI conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{EPI} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{EPI}EPI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{EPI,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on EPI. Stocks are finally grouped into five EPI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EPI trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on EPI and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the EPI signal in these Fama-MacBeth regressions exceed

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

-1.22, with the minimum t-statistic occurring when controlling for Sales-to-price. Controlling for all six closely related anomalies, the t-statistic on EPI is -0.66.

Similarly, Table 5 reports results from spanning tests that regress returns to the EPI strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the EPI strategy earns alphas that range from -27–10bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is -4.00, which is achieved when controlling for Sales-to-price. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the EPI trading strategy achieves an alpha of -21bps/month with a t-statistic of -3.56.

7 Does EPI add relative to the whole zoo?

Finally, we can ask how much adding EPI to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 154 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 154 anomalies augmented with the EPI signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 154-anomaly combination strategy grows to \$2560.30, while \$1 investment in the combination strategy that includes EPI grows to \$3165.09.

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which EPI is available.

8 Conclusion

This study provides a comprehensive analysis of Equity Production Intensity (EPI) as a predictor of cross-sectional stock returns, employing the rigorous testing framework established by Novy-Marx and Velikov (2023). Our findings reveal that while EPI demonstrates some predictive capability with a modest Sharpe ratio of 0.25 (0.23 net of costs), its economic significance appears limited when subjected to thorough risk adjustment and comparison with existing factors.

The key findings of our analysis present a nuanced picture of EPI’s effectiveness. The strategy generates positive raw returns, as evidenced by the reasonable Sharpe ratios, suggesting that EPI contains some information relevant to future stock returns. However, the signal’s predictive power diminishes substantially when controlling for established risk factors. The negative alpha of -18 bps per month relative to the Fama-French five-factor model plus momentum, though marginally significant, indicates that much of EPI’s return predictability is subsumed by existing factors. More concerning is the highly significant negative alpha of -21 bps per month (t-statistic of -3.56) when controlling for closely related strategies, suggesting that EPI offers limited incremental information beyond what is already captured by similar production and operational efficiency measures.

From a practical perspective, these results have important implications for both academic researchers and investment practitioners. While EPI may serve as a useful characteristic for understanding firm fundamentals and production dynamics, its standalone value as an alpha-generating signal appears questionable. The modest net Sharpe ratio of 0.23, combined with negative risk-adjusted returns, suggests that implementing an EPI-based strategy would likely not justify the associated transaction costs and operational complexity in real-world portfolio management. Investors seeking exposure to production efficiency factors would likely achieve superior results through existing, more robust signals such as operating leverage or cash-flow-based

measures.

Several limitations of this study warrant consideration. First, our analysis is confined to the U.S. equity market, and the effectiveness of EPI in international markets remains unexplored. Second, the sample period and specific implementation choices, while following established protocols, may influence the results. Third, our analysis focuses on linear relationships and may not capture potential non-linearities or conditional effects of EPI across different market regimes or business cycles.

Future research should address these limitations through several avenues. Examining EPI's performance in international markets could reveal whether its predictive power varies across different institutional and economic environments. Investigating the time-varying nature of EPI's effectiveness, particularly during periods of technological disruption or economic stress, may uncover conditional relationships not captured in our unconditional analysis. Additionally, exploring potential interactions between EPI and other firm characteristics, such as firm size, industry classification, or financial constraints, could identify specific contexts where the signal provides meaningful alpha. Finally, decomposing EPI into its constituent components might reveal which aspects of production intensity drive any predictive power, potentially leading to refined measures with stronger return predictability. Despite its limitations as a standalone predictor, EPI contributes to our understanding of the relationship between firm production characteristics and asset prices, adding to the growing literature on the intersection of real economic activity and financial markets.

Figure 1: Times series of EPI percentiles and coverage. This figure plots descriptive statistics for EPI. Panel A shows cross-sectional percentiles of EPI over the sample. Panel B plots the monthly coverage of EPI relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on EPI. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the EPI strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.19 [1.94]	0.13 [1.37]	0.05 [0.52]	0.02 [0.17]	-0.17 [-2.09]	-0.18 [-2.18]
Quintile	NYSE	EW	0.19 [1.96]	0.10 [1.04]	-0.00 [-0.01]	0.04 [0.42]	-0.13 [-1.59]	-0.09 [-1.05]

Table 3: Conditional sort on size and EPI

This table presents results for conditional double sorts on size and EPI. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on EPI. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high EPI and short stocks with low EPI. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	EPI Quintiles					EPI Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the EPI with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the EPI trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations. This figure plots a name histogram of correlations of 210 filtered anomaly signals with EPI. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of EPI conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{EPI} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{EPI}EPI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{EPI,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on EPI. Stocks are finally grouped into five EPI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EPI trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on EPI. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{EPI}EPI_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Operating leverage, Sales-to-price, Cash-flow to price variance, Advertising Expense, Order backlog, Cash to assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the EPI trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{EPI} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Operating leverage, Sales-to-price, Cash-flow to price variance, Advertising Expense, Order backlog, Cash to assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 154 anomalies. The red solid lines indicate combination trading strategies that utilize the 154 anomalies as well as EPI. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
