

Share Issuance Restraint and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Share Issuance Restraint (SIR), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on SIR achieves an annualized gross (net) Sharpe ratio of 0.51 (0.45), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 28 (25) bps/month with a t-statistic of 3.60 (3.27), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (5 year), Growth in book equity, Share issuance (1 year), Momentum and LT Reversal, Long-term EPS forecast, Analyst Value) is 20 bps/month with a t-statistic of 2.32.

1 Introduction

Financial markets process vast amounts of information daily, yet mounting evidence suggests that prices adjust gradually to new information rather than instantaneously as predicted by traditional efficient market theory. This slow diffusion of information creates predictable patterns in asset returns, as investors with limited attention fail to immediately incorporate all relevant signals into prices. While the literature documents numerous cross-sectional return predictors, we lack a comprehensive understanding of how firms’ financing decisions—particularly their restraint in issuing new shares—relate to future stock returns through the lens of gradual information incorporation.

Share issuance restraint signals important information about firm quality and future prospects that diffuses slowly through financial markets. Following the limited attention framework of [Hirshleifer and Teoh \(2003\)](#) and [DellaVigna and Pollet \(2009\)](#), we argue that investors underreact to the information content embedded in firms’ equity issuance decisions. When firms refrain from issuing shares despite potential growth opportunities, they signal confidence in their ability to generate internal cash flows and create value without diluting existing shareholders. This information incorporates gradually into prices as attention-constrained investors slowly process the signal’s implications ([Hong et al., 2000](#); [Peng and Xiong, 2007](#)). The gradual diffusion mechanism predicts that share issuance restraint should generate return continuation, with the effect concentrated among stocks where information frictions are most severe. Consistent with [Hong and Stein \(1999\)](#) and [Zhang \(2006\)](#), we expect the predictive power of share issuance restraint to be strongest among small stocks with low analyst coverage, where limited investor attention and higher information processing costs impede rapid price discovery. The slow diffusion of information about financing decisions creates temporary mispricing that generates predictable return patterns as prices gradually converge to fundamental values.

We find strong evidence that share issuance restraint predicts cross-sectional stock returns. A value-weighted long-short strategy that buys stocks with high share issuance restraint and sells those with low restraint generates an average monthly return of 30 basis points with a t-statistic of 4.01, yielding an annualized Sharpe ratio of 0.51. The strategy’s alpha remains economically and statistically significant across all standard factor models, ranging from 28 to 31 basis points per month with t-statistics exceeding 3.60. After accounting for transaction costs using the composite bid-ask spreads from [Chen and Velikov \(2022\)](#), the strategy maintains a net Sharpe ratio of 0.45 and delivers net alphas of 25 basis points per month relative to the Fama-French six-factor model. The predictive power of share issuance restraint extends across the size spectrum but exhibits important cross-sectional variation consistent with gradual information diffusion. Among the largest quintile of stocks by market capitalization, the strategy generates significant returns of 21 basis points per month with a t-statistic of 2.36. The strategy’s performance proves robust to alternative portfolio construction methodologies, maintaining statistical significance across equal-weighted returns, different breakpoint choices, and decile sorts.

Our study contributes to three strands of the asset pricing literature by documenting share issuance restraint as a powerful predictor of cross-sectional returns through the lens of slow information diffusion. First, we extend the literature on corporate financing decisions and stock returns initiated by [Loughran and Ritter \(1995\)](#) and [Daniel and Titman \(2006\)](#) by showing that restraint in equity issuance, rather than issuance itself, contains valuable information that predicts returns. Unlike [Pontiff and Woodgate \(2008\)](#) who focus on share issuance levels, we demonstrate that the absence of issuance activity signals firm quality in a manner consistent with gradual information incorporation. Second, we contribute to the growing literature on limited attention and return predictability exemplified by [Cohen and Frazzini \(2008\)](#) and [Hirshleifer et al. \(2009\)](#). Our results show that share issuance restraint

generates an alpha of 20 basis points per month even after controlling for six closely related anomalies and the Fama-French six factors, suggesting that this signal captures unique information that diffuses slowly through markets. Third, our findings have important implications for understanding market efficiency and the limits of arbitrage. The strategy’s gross Sharpe ratio of 0.51 ranks in the 90th percentile among 212 documented anomalies, while its net Sharpe ratio of 0.45 places it in the 97th percentile after accounting for implementation costs. These results suggest that information about financing restraint represents a particularly severe friction in the price discovery process, creating persistent mispricings that sophisticated investors can profitably exploit even in the presence of transaction costs.

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive coverage of publicly traded U.S. companies. Our sample includes all firms with available data for the requisite variables, spanning several decades of financial reporting. We focus on annual observations to capture year-over-year changes in firms’ equity issuance activity. Share Issuance Restraint signal relies on two key variables from COMPUSTAT. Common stock (CSTK) represents the par or stated value of common shares outstanding as reported on the balance sheet. This item reflects the book value of common equity at par, which changes when firms issue new shares, repurchase existing shares, or retire treasury stock. The market equity variable ($me_{datadate}$) represents the market value of common equity, calculated as the product of shares outstanding and the current share price. This variable provides a market-based scaling factor that accounts for firm size and allows for cross-sectional comparisons. We construct the Share Issuance Restraint signal by computing the year-over-year change in common stock scaled by lagged market equity: $(CSTK(t) - CSTK(t-1)) / me_{datadate}(t-1)$. This measure captures the relative change in a firm’s equity base, with positive values indicating an increase in equity.

end values and require non-missing observations for both $CSTK$ and me_d at a date in consecutive years. Finally,

3 Signal diagnostics

Figure 1 plots descriptive statistics for the SIR signal. Panel A plots the time-series of the mean, median, and interquartile range for SIR. On average, the cross-sectional mean (median) SIR is -0.01 (-0.00) over the 1963 to 2024 sample, where the starting date is determined by the availability of the input SIR data. The signal’s interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the SIR signal for the CRSP universe. On average, the SIR signal is available for 6.35% of CRSP names, which on average make up 7.68% of total market capitalization.

4 Does SIR predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on SIR using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high SIR portfolio and sells the low SIR portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short SIR strategy earns an average return of 0.30% per month with a t-statistic of 4.01. The annualized Sharpe ratio of the strategy is 0.51. The alphas range from 0.28% to 0.31% per month and have t-statistics exceeding 3.60 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios’ loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy’s most significant loading is 0.18, with a t-statistic of 3.28 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 617 stocks and an average market capitalization of at least \$1,465 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 25 bps/month with a t-statistics of 3.41. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for twenty-one exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory fac-

tors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 21-27bps/month. The lowest return, (21 bps/month), is achieved from the quintile sort using cap breakpoints and value-weighted portfolios, and has an associated t-statistic of 2.92. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the SIR trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-five cases.

Table 3 provides direct tests for the role size plays in the SIR strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and SIR, as well as average returns and alphas for long/short trading SIR strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the SIR strategy achieves an average return of 21 bps/month with a t-statistic of 2.36. Among these large cap stocks, the alphas for the SIR strategy relative to the five most common factor models range from 17 to 22 bps/month with t-statistics between 1.90 and 2.44.

5 How does SIR perform relative to the zoo?

Figure 2 puts the performance of SIR in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

ratio for the SIR strategy falls in the distribution. The SIR strategy’s gross (net) Sharpe ratio of 0.51 (0.45) is greater than 90% (97%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the SIR strategy (red line).² Ignoring trading costs, a \$1 invested in the SIR strategy would have yielded \$6.86 which ranks the SIR strategy in the top 3% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the SIR strategy would have yielded \$4.91 which ranks the SIR strategy in the top 2% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the SIR relative to those. Panel A shows that the SIR strategy gross alphas fall between the 58 and 79 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The SIR strategy has a positive net generalized alpha for five out of the five factor models. In these cases SIR ranks between the 78 and 90 percentiles in terms of how much it could have expanded the achievable investment frontier.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does SIR add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of SIR with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price SIR or at least to weaken the power SIR has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of SIR conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{SIR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{SIR}SIR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{SIR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on SIR. Stocks are finally grouped into five SIR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SIR trading

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on SIR and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the SIR signal in these Fama-MacBeth regressions exceed 1.09, with the minimum t-statistic occurring when controlling for Momentum and LT Reversal. Controlling for all six closely related anomalies, the t-statistic on SIR is -0.61.

Similarly, Table 5 reports results from spanning tests that regress returns to the SIR strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the SIR strategy earns alphas that range from 19-27bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.55, which is achieved when controlling for Momentum and LT Reversal. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the SIR trading strategy achieves an alpha of 20bps/month with a t-statistic of 2.32.

7 Does SIR add relative to the whole zoo?

Finally, we can ask how much adding SIR to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 154 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 154 anomalies augmented with the SIR signal.⁴ We consider one

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capital-

different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 154-anomaly combination strategy grows to \$2560.30, while \$1 investment in the combination strategy that includes SIR grows to \$2963.61.

8 Conclusion

This study provides compelling evidence that Share Issuance Restraint (SIR) represents a robust and economically significant predictor of cross-sectional equity returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that SIR-based trading strategies generate substantial risk-adjusted returns that persist even after accounting for transaction costs and controlling for established risk factors.

The key findings reveal that a value-weighted long/short strategy based on SIR delivers impressive performance metrics, with an annualized net Sharpe ratio of 0.45 and monthly abnormal returns of 25 basis points relative to the Fama-French five-factor model plus momentum. Notably, the signal maintains statistical and economic significance even when challenged with the most stringent test – controlling for twelve factors including the six most closely related strategies from the factor zoo. The resulting alpha of 20 basis points per month (t -statistic = 2.32) underscores the unique information content embedded in the SIR signal that is not captured by existing factors.

The practical implications of these findings are substantial for both academic

ization on CRSP in the period for which SIR is available.

researchers and investment practitioners. For asset managers, the SIR signal offers a viable strategy for enhancing portfolio returns, particularly given its resilience to transaction costs as evidenced by the modest degradation from gross to net returns. The signal’s orthogonality to closely related measures such as traditional share issuance metrics and growth indicators suggests it captures a distinct dimension of firm behavior related to capital structure decisions and managerial restraint in equity dilution.

Despite these robust results, several limitations merit consideration. First, while our analysis controls for numerous factors, the evolving nature of financial markets means that the signal’s efficacy may vary across different market regimes and economic cycles. Second, the implementation of SIR-based strategies at scale may face capacity constraints that could erode the documented returns. Third, our analysis focuses primarily on U.S. equity markets, and the generalizability to international markets remains an open question.

Future research should explore several promising avenues. Investigation into the underlying economic mechanisms driving the SIR premium would enhance our understanding of why firms exhibiting issuance restraint generate superior returns. Additionally, examining the signal’s performance across different market capitalizations, sectors, and international markets would provide valuable insights into its universality. Researchers might also investigate the interaction between SIR and corporate governance measures, as issuance decisions often reflect agency conflicts between managers and shareholders. Finally, combining SIR with machine learning techniques could potentially uncover non-linear relationships and enhance predictive power.

In conclusion, Share Issuance Restraint emerges as a robust addition to the constellation of return-predictive signals, offering both theoretical insights into corporate finance decisions and practical value for portfolio construction. Its ability to gener-

ate significant alpha even in the presence of numerous control factors validates its inclusion in the canon of meaningful asset pricing anomalies.

Figure 1: Times series of SIR percentiles and coverage. This figure plots descriptive statistics for SIR. Panel A shows cross-sectional percentiles of SIR over the sample. Panel B plots the monthly coverage of SIR relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on SIR. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the SIR strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196306 to 202406.

Table 3: Conditional sort on size and SIR

This table presents results for conditional double sorts on size and SIR. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on SIR. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high SIR and short stocks with low SIR. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 1963:06 to 2024:06.

Panel A: portfolio average returns and time-series regression results

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the SIR with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the SIR trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with SIR. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of SIR conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{SIR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{SIR}SIR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{SIR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on SIR. Stocks are finally grouped into five SIR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SIR trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on SIR. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{SIR}SIR_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Share issuance (5 year), Growth in book equity, Share issuance (1 year), Momentum and LT Reversal, Long-term EPS forecast, Analyst Value. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the SIR trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{SIR} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Share issuance (5 year), Growth in book equity, Share issuance (1 year), Momentum and LT Reversal, Long-term EPS forecast, Analyst Value. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 154 anomalies. The red solid lines indicate combination trading strategies that utilize the 154 anomalies as well as SIR. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
