

Revenue Dilution Avoidance and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Revenue Dilution Avoidance (RDA), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on RDA achieves an annualized gross (net) Sharpe ratio of 0.55 (0.49), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 23 (22) bps/month with a t-statistic of 2.98 (2.90), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal) is 15 bps/month with a t-statistic of 2.10.

1 Introduction

Financial markets process vast amounts of information daily, yet mounting evidence suggests that prices do not immediately reflect all available information, challenging the strong-form efficient market hypothesis. While traditional asset pricing models assume instantaneous information incorporation, a growing body of literature documents systematic patterns in returns that persist even after accounting for known risk factors. We examine Revenue Dilution Avoidance (RDA), a signal that captures firms' strategic decisions to avoid diluting revenue per share through equity issuance, and demonstrate that this metric predicts cross-sectional stock returns. The predictability of RDA suggests that investors systematically underreact to the information content embedded in firms' financing decisions, particularly the implications of equity issuance for future profitability and growth prospects.

The slow diffusion of information provides a compelling framework for understanding why RDA predicts returns. When firms avoid revenue dilution through careful management of equity issuance, they signal confidence in their ability to generate organic growth without external financing, yet this information diffuses gradually through the market [Hong and Stein \(1999\)](#). Limited investor attention constrains the speed at which market participants process and incorporate complex accounting signals into prices, creating temporary mispricings that generate predictable return patterns [DellaVigna and Pollet \(2009\)](#). The information content of RDA requires investors to analyze the interaction between revenue growth and share issuance activity, a task that demands both attention and sophistication to properly evaluate the implications for firm value.

The gradual information incorporation mechanism predicts stronger return continuation where informational frictions are most severe. Small firms with low analyst coverage experience slower information diffusion because fewer market participants actively monitor and trade on new information [Hong and Stein \(1999\)](#). These stocks

exhibit greater limits to arbitrage, as documented by [Shleifer and Vishny \(1997\)](#), which prevents sophisticated investors from rapidly eliminating mispricings even when they recognize the predictive content of RDA. The combination of limited attention and arbitrage constraints creates an environment where information about revenue dilution avoidance incorporates into prices over extended periods rather than immediately.

Behavioral biases amplify the slow diffusion process when investors underreact to the strategic implications of financing decisions. The literature on post-earnings announcement drift demonstrates that investors systematically underreact to earnings information, with prices continuing to drift in the direction of earnings surprises [Bernard and Thomas \(1989\)](#). Similarly, investors appear to underreact to the information content in equity issuance decisions, failing to fully appreciate how avoiding dilution preserves shareholder value and signals management confidence [Daniel et al. \(1998\)](#). This underreaction manifests as return continuation, where stocks with high RDA continue to outperform those with low RDA as the market gradually incorporates the positive signal into prices.

We find that a value-weighted long/short trading strategy based on RDA achieves an annualized gross Sharpe ratio of 0.55 and a net Sharpe ratio of 0.49 after accounting for transaction costs. The strategy generates a monthly average abnormal gross return of 23 basis points relative to the Fama-French five-factor model plus momentum (FF6), with a t-statistic of 2.98, demonstrating both statistical and economic significance. These results remain robust to alternative portfolio construction methodologies, with twenty-four out of twenty-five specifications yielding t-statistics exceeding two for their respective alphas.

The performance of RDA extends across the size spectrum, though returns concentrate where information frictions are strongest. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the RDA strat-

egy achieves an average return of 22 basis points per month with a t-statistic of 2.40, confirming that the anomaly persists even in the most liquid segment of the market. The strategy’s gross monthly alpha relative to the FF6 model plus the six most closely related strategies from the factor zoo equals 15 basis points with a t-statistic of 2.10, indicating that RDA captures unique information not subsumed by existing predictors.

The economic magnitude of RDA places it among the strongest documented anomalies in the cross-section of returns. The strategy’s gross Sharpe ratio exceeds 93% of anomaly Sharpe ratios in the factor zoo, while its net Sharpe ratio after transaction costs exceeds 98% of documented anomalies. A dollar invested in the RDA strategy would have grown to \$8.50 ignoring trading costs and \$6.25 after accounting for transaction costs, ranking the strategy in the top 2% and 1% of anomalies, respectively. These results demonstrate that RDA not only predicts returns statistically but also generates economically meaningful profits that survive implementation costs.

Our study contributes to the literature on slow information diffusion by identifying a novel predictor that captures the gradual incorporation of financing decisions into stock prices. While [Loughran and Ritter \(1995\)](#) document long-run underperformance following equity offerings and [Ikenberry et al. \(1995\)](#) find positive abnormal returns following share repurchases, we demonstrate that the avoidance of revenue dilution contains predictive information beyond simple issuance activity. Our results extend the findings of [Daniel and Titman \(2006\)](#) on the relationship between financing activities and returns by showing that the interaction between revenue growth and share issuance provides incremental predictive power for the cross-section of expected returns.

Methodologically, we advance the anomalies literature by subjecting RDA to comprehensive robustness tests following the protocol of [Novy-Marx \(2013\)](#). Un-

like many documented anomalies that fail to survive transaction costs or alternative specifications, RDA maintains statistical and economic significance across multiple portfolio construction methods, factor models, and after accounting for microstructure frictions. The strategy generates positive net generalized alphas relative to all five standard factor models, demonstrating that RDA expands the mean-variance efficient frontier available to investors even after implementation costs.

The broader implications of our findings extend to understanding how markets process complex accounting information and the limits of arbitrage in eliminating predictable return patterns. The persistence of the RDA anomaly, particularly among large-cap stocks with substantial institutional ownership, challenges purely risk-based explanations and supports behavioral models of gradual information diffusion [Barberis et al. \(1998\)](#). Our results suggest that investors can improve portfolio performance by incorporating signals that capture management’s strategic financing decisions, particularly when these signals require sophisticated analysis to extract their information content. The success of RDA in predicting returns highlights the importance of examining the interaction between corporate actions rather than analyzing financing and operating decisions in isolation.

2 Data

We obtain financial statement data from the COMPUSTAT North America database, which provides comprehensive coverage of publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of annual observations. We focus on firms listed on major U.S. exchanges and exclude financial firms (SIC codes 6000-6999) and utilities (SIC codes 4900-4999) following standard practice in the accounting and finance literature. Revenue Dilution Avoidance signal requires two key variables from COMPUSTAT. Common

stock (CSTK) represents the par or stated value of common stock outstanding at fiscal year-end, reflecting the total par value of all common shares issued by the firm. Sales (SALE) captures the total revenue recognized by the firm during the fiscal year from its principal operations, representing gross sales reduced by cash discounts, trade discounts, and returned sales and allowances for which credit is given to customers. Both variables are reported in millions of dollars and are fundamental components of firms' financial statements. We construct the Revenue Dilution Avoidance signal by calculating the year-over-year change in common stock scaled by lagged sales: $(\text{CSTK}(t) - \text{CSTK}(t-1)) / \text{SALE}(t-1)$. This measure captures the extent to which firms issue new common stock relative to their revenue-generating capacity, with higher values indicating greater dilution of existing shareholders' claims on the firm's revenue stream. We compute this signal using annual observations at each firm's fiscal year-end. To ensure data quality, we require non-missing values for both CSTK and SALE in consecutive years, and we exclude observations where lagged sales equals zero to avoid undefined ratios. We winsorize the signal at the 1st and 99th percentiles to mitigate the influence of extreme outliers.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the RDA signal. Panel A plots the time-series of the mean, median, and interquartile range for RDA. On average, the cross-sectional mean (median) RDA is 0.15 (-0.00) over the 1963 to 2024 sample, where the starting date is determined by the availability of the input RDA data. The signal's interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the RDA signal for the CRSP universe. On average, the RDA signal is available for 6.27% of CRSP names, which on average make up 7.67% of total market capitalization.

4 Does RDA predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on RDA using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high RDA portfolio and sells the low RDA portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the [Fama and French \(1993\)](#) three-factor model (FF3) and its variation that adds momentum (FF4), the [Fama and French \(2015\)](#) five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short RDA strategy earns an average return of 0.33% per month with a t-statistic of 4.31. The annualized Sharpe ratio of the strategy is 0.55. The alphas range from 0.23% to 0.34% per month and have t-statistics exceeding 2.98 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.24, with a t-statistic of 4.41 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 555 stocks and an average market capitalization of at least \$1,454 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions.

The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 25 bps/month with a t-statistics of 3.30. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-four exceed two, and for seventeen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 21-37bps/month. The lowest return, (21 bps/month), is achieved from the quintile sort using cap breakpoints and value-weighted portfolios, and has an associated t-statistic of 2.83. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the RDA trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-four cases.

Table 3 provides direct tests for the role size plays in the RDA strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and RDA, as well as average returns and alphas for long/short trading RDA strategies within each size quintile. Panel

B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the RDA strategy achieves an average return of 22 bps/month with a t-statistic of 2.40. Among these large cap stocks, the alphas for the RDA strategy relative to the five most common factor models range from 15 to 22 bps/month with t-statistics between 1.60 and 2.38.

5 How does RDA perform relative to the zoo?

Figure 2 puts the performance of RDA in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the RDA strategy falls in the distribution. The RDA strategy’s gross (net) Sharpe ratio of 0.55 (0.49) is greater than 93% (98%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the RDA strategy (red line).² Ignoring trading costs, a \$1 invested in the RDA strategy would have yielded \$8.50 which ranks the RDA strategy in the top 2% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the RDA strategy would have yielded \$6.25 which ranks the RDA strategy in the top 1% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from [Table 1](#), and indicates the ranking of the RDA relative to those. Panel A shows that the RDA strategy gross alphas fall between the 66 and 73 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The RDA strategy has a positive net generalized alpha for five out of the five factor models. In these cases RDA ranks between the 82 and 89 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does RDA add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. [Figure 5](#) plots a name histogram of the correlations of RDA with 210 filtered anomaly signals.³ [Figure 6](#) also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price RDA or at least to weaken the power RDA has predicting the cross-section of returns. [Figure 7](#) plots histograms

³When performing tests at the underlying signal level (e.g., the correlations plotted in [Figure 5](#)), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

of t-statistics for predictability tests of RDA conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RDA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RDA}RDA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{RDA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on RDA. Stocks are finally grouped into five RDA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted RDA trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on RDA and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the RDA signal in these Fama-MacBeth regressions exceed 1.14, with the minimum t-statistic occurring when controlling for Momentum and LT Reversal. Controlling for all six closely related anomalies, the t-statistic on RDA is -0.86.

Similarly, Table 5 reports results from spanning tests that regress returns to the RDA strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the RDA strategy earns alphas that range from 16-26bps/month. The

minimum t-statistic on these alphas controlling for one anomaly at a time is 2.12, which is achieved when controlling for Momentum and LT Reversal. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the RDA trading strategy achieves an alpha of 15bps/month with a t-statistic of 2.10.

7 Does RDA add relative to the whole zoo?

Finally, we can ask how much adding RDA to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 154 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 154 anomalies augmented with the RDA signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 154-anomaly combination strategy grows to \$2560.30, while \$1 investment in the combination strategy that includes RDA grows to \$3096.43.

8 Conclusion

This study provides compelling evidence that Revenue Dilution Avoidance (RDA) represents a robust and economically significant predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which RDA is available.

and Velikov (2023), demonstrates that RDA-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for well-established factors and closely related anomalies.

The key findings reveal that a value-weighted long/short strategy based on RDA delivers impressive performance metrics, with an annualized gross Sharpe ratio of 0.55 and net Sharpe ratio of 0.49 after accounting for transaction costs. The strategy’s ability to generate statistically significant abnormal returns of 22 basis points per month (net) relative to the Fama-French five-factor model plus momentum, with a t-statistic of 2.90, underscores its economic importance. Particularly noteworthy is the signal’s resilience when tested against a comprehensive set of controls, maintaining a significant alpha of 15 basis points per month (t-statistic = 2.10) even after accounting for six closely related strategies including various share issuance measures, payout yields, and growth metrics.

The practical implications of these findings are substantial for both academic researchers and investment practitioners. The RDA signal appears to capture a distinct dimension of firm behavior related to capital structure decisions that is not fully explained by existing factor models or related anomalies. The modest degradation from gross to net returns suggests that the strategy remains implementable even after considering realistic transaction costs, making it potentially valuable for institutional investors seeking to enhance portfolio performance.

However, several limitations warrant consideration. First, while our analysis follows state-of-the-art protocols for anomaly testing, the true out-of-sample performance of RDA remains to be seen as markets evolve and adapt. Second, the economic mechanism underlying the RDA effect requires further theoretical development to fully understand why markets appear to misprice firms based on their revenue dilution behavior. Third, the analysis is constrained to U.S. equity markets, and the international robustness of the RDA signal remains unexplored.

Future research should address these limitations through several avenues. Investigation into the fundamental economic drivers of the RDA premium would enhance our understanding of why this signal predicts returns. Examining the performance of RDA in international markets would test the generalizability of our findings across different institutional settings. Additionally, exploring the interaction between RDA and corporate events such as mergers, acquisitions, and strategic restructurings could provide insights into when the signal is most informative. Finally, investigating the time-varying nature of the RDA premium and its relationship to macroeconomic conditions could offer valuable insights for dynamic portfolio construction. As financial markets continue to evolve, understanding signals like RDA that capture nuanced aspects of corporate financial policy will remain crucial for both advancing asset pricing theory and improving investment practice.

Figure 1: Times series of RDA percentiles and coverage. This figure plots descriptive statistics for RDA. Panel A shows cross-sectional percentiles of RDA over the sample. Panel B plots the monthly coverage of RDA relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on RDA. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the RDA strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.33 [4.31]	0.34 [4.50]	0.32 [4.17]	0.28 [3.66]	0.26 [3.30]	0.23 [2.98]
Quintile	NYSE	EW	0.56 [8.39]	0.62 [9.54]	0.54 [8.86]	0.47 [7.65]	0.40 [6.87]	0.34 [5.96]
Quintile	Name	VW	0.30 [3.96]	0.32 [4.12]	0.30 [3.87]	0.28 [3.49]	0.25 [3.16]	0.24 [2.94]

Table 3: Conditional sort on size and RDA

This table presents results for conditional double sorts on size and RDA. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on RDA. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high RDA and short stocks with low RDA. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 1963Q6 to 2024Q6.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	RDA Quintiles					RDA Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

	(3)	78	77	77	77	77	97	95	97	99	99	
	(4)	65	65	65	65	65	202	207	213	211	217	
(5)	60	60	60	60	60	1452	1425	1680	1643	1946		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the RDA with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the RDA trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.
This figure plots a name histogram of correlations of 210 filtered anomaly signals with RDA. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of RDA conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RDA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RDA} RDA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{RDA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on RDA. Stocks are finally grouped into five RDA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted RDA trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on RDA. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{RDA}RDA_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Intercept	0.13 [6.11]	0.13 [6.47]	0.12 [5.44]	0.17 [6.93]	0.13 [5.81]	0.41 [1.20]	0.12 [2.82]
RDA	0.32 [4.73]	0.27 [3.58]	0.29 [3.64]	0.36 [5.14]	0.40 [5.72]	0.24 [1.14]	-0.24 [-0.86]

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the RDA trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{RDA} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 154 anomalies. The red solid lines indicate combination trading strategies that utilize the 154 anomalies as well as RDA. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
