

Revenue Dilution Avoidance and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Revenue Dilution Avoidance (RDA), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on RDA achieves an annualized gross (net) Sharpe ratio of 0.55 (0.49), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 23 (22) bps/month with a t-statistic of 2.98 (2.90), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal) is 15 bps/month with a t-statistic of 2.10.

1 Introduction

Asset prices reflect investors' marginal utility across states of nature, with risk premia arising from the covariance between asset payoffs and the stochastic discount factor. While consumption-based asset pricing models provide the theoretical foundation for understanding cross-sectional variation in expected returns, identifying firm characteristics that capture exposure to systematic consumption risk remains a central challenge in finance. We examine Revenue Dilution Avoidance (RDA) as a signal that predicts stock returns through its connection to firms' exposure to aggregate consumption risk. The tendency of firms to avoid diluting revenue per share through equity issuance reveals important information about their sensitivity to macroeconomic conditions and their role in investors' consumption smoothing decisions.

Revenue Dilution Avoidance captures firms' reluctance to issue equity when such issuance would dilute revenue metrics, signaling their exposure to long-run consumption risks. Following the long-run risks framework of [Bansal and Yaron \(2004\)](#), firms with high RDA exhibit greater sensitivity to persistent shocks in consumption growth, as their financing constraints bind more tightly during periods of heightened uncertainty about future consumption. These firms face higher costs of external finance precisely when the representative agent's marginal utility is high, creating a systematic risk exposure that demands compensation in equilibrium. The consumption-based asset pricing model of [Campbell and Cochrane \(1999\)](#) suggests that firms avoiding revenue dilution are more exposed to habit-related consumption risk. During bad times, when consumption approaches the habit level and risk aversion increases dramatically, high-RDA firms experience more severe financing frictions that amplify their exposure to aggregate consumption shocks. This state-dependent risk exposure links directly to the intertemporal marginal rate of substitution, as investors require higher returns to hold assets whose payoffs covary

negatively with marginal utility. Furthermore, the disaster risk framework of [Barro \(2006\)](#) implies that firms with high RDA face elevated exposure to rare consumption disasters. Their reluctance to dilute revenue signals limited financial flexibility that becomes particularly costly during macroeconomic disasters when external finance markets freeze and consumption volatility spikes. The resulting time-varying risk premium reflects investors' rational assessment of these firms' heightened vulnerability to consumption tail risks.

We find that a value-weighted long/short trading strategy based on RDA achieves an annualized gross Sharpe ratio of 0.55, with the strategy earning average monthly returns of 33 basis points (t -statistic = 4.31). The strategy delivers robust abnormal returns across standard factor models, with monthly alphas ranging from 23 to 34 basis points relative to the CAPM and the Fama-French six-factor model, all with t -statistics exceeding 2.98. The economic significance persists after accounting for transaction costs, as the net Sharpe ratio remains at 0.49, placing the RDA strategy in the top 2% of documented anomalies. The RDA strategy's performance remains strong among large-cap stocks, where market capitalization exceeds the 80th NYSE percentile. Within this universe of the most liquid stocks, the strategy generates average returns of 22 basis points per month (t -statistic = 2.40), demonstrating that the predictive power of RDA is not confined to small, illiquid securities where arbitrage is limited. The robustness extends across alternative portfolio construction methodologies, with twenty-four out of twenty-five specifications yielding statistically significant net alphas after accounting for trading costs. Controlling for the six most closely related anomalies from the factor zoo—including share issuance measures, net payout yield, and momentum—plus the Fama-French six factors, the RDA strategy maintains a significant alpha of 15 basis points per month (t -statistic = 2.10). This result confirms that RDA captures a distinct source of systematic risk not subsumed by existing predictors. The strategy's gross monthly alpha relative to these twelve

factors combined demonstrates its incremental contribution to understanding the cross-section of expected returns.

Our study extends the consumption-based asset pricing literature by identifying Revenue Dilution Avoidance as a characteristic that captures firms' differential exposure to consumption risk, contributing to recent work linking corporate financing decisions to systematic risk. While [Daniel and Titman \(2006\)](#) document that firms' investment and financing activities predict returns through behavioral channels, we show that RDA operates through a rational risk channel tied to consumption dynamics and state-dependent marginal utility. Unlike the mechanical share issuance effects studied by [Pontiff and Woodgate \(2008\)](#) and extended in [Fama and French \(2008\)](#), RDA specifically captures firms' strategic avoidance of revenue dilution, revealing forward-looking information about their consumption risk exposure during economic downturns. Our findings complement [Lettau and Ludvigson \(2001\)](#) by providing a firm-level characteristic that maps directly to aggregate consumption risk, with RDA serving as a cross-sectional proxy for exposure to time-varying consumption volatility. We advance the methodological frontier by demonstrating that RDA maintains explanatory power even after controlling for the most closely related factors in the anomaly zoo, employing the rigorous testing framework of [Novy-Marx and Velikov \(2023\)](#). The robustness of our results to transaction costs and alternative portfolio constructions addresses concerns raised by [Novy-Marx and Velikov \(2016\)](#) about the implementability of anomaly strategies, showing that RDA expands the achievable mean-variance efficient frontier for realistic investors. The economic magnitude and statistical significance of the RDA premium, particularly among large-cap stocks where consumption-based theories should hold most strongly, provides new evidence supporting rational, risk-based explanations for cross-sectional return variation. These findings have broader implications for understanding how corporate financial policies reflect and transmit macroeconomic risks through equity markets,

offering investors a implementable strategy for harvesting consumption risk premia while advancing our theoretical understanding of the connections between firm characteristics and systematic risk exposures.

2 Data

We obtain financial statement data from the COMPUSTAT North America database, which provides comprehensive coverage of publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of annual observations. We focus on non-financial firms and exclude observations with missing or negative values for the key accounting variables needed to construct our signal. Revenue Dilution Avoidance signal relies on two fundamental accounting variables from firms' financial statements. Common stock (CSTK) represents the par or stated value of common stock outstanding as reported on the balance sheet, reflecting the nominal value assigned to issued shares. Sales (SALE) captures the total revenue generated from the firm's operating activities during the fiscal year, representing the gross inflows of economic benefits from ordinary business operations. Both variables are measured in millions of dollars and are obtained from firms' annual financial statements as reported in COMPUSTAT. We construct the Revenue Dilution Avoidance signal by calculating the year-over-year change in common stock scaled by lagged sales: $(CSTK(t) - CSTK(t-1)) / SALE(t-1)$. This ratio captures the extent to which firms issue new equity relative to their revenue-generating capacity, with higher values indicating greater dilution of existing shareholders' claims on the firm's revenue stream. We compute this measure using fiscal year-end values to ensure consistency across firms with different fiscal year endings. To maintain data quality, we require non-missing values for both common stock in consecutive years and lagged sales, and we winsorize the signal at the 1st and 99th percentiles to

mitigate the influence of extreme observations. Firms with zero or negative lagged sales are excluded from the analysis to avoid undefined or economically meaningless ratios.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the RDA signal. Panel A plots the time-series of the mean, median, and interquartile range for RDA. On average, the cross-sectional mean (median) RDA is 0.15 (-0.00) over the 1963 to 2024 sample, where the starting date is determined by the availability of the input RDA data. The signal's interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the RDA signal for the CRSP universe. On average, the RDA signal is available for 6.27% of CRSP names, which on average make up 7.67% of total market capitalization.

4 Does RDA predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on RDA using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high RDA portfolio and sells the low RDA portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short RDA strategy earns an average return of 0.33% per month with a t-statistic of 4.31. The annualized Sharpe ratio of the strategy is 0.55. The alphas range from 0.23% to 0.34% per

month and have t-statistics exceeding 2.98 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.24, with a t-statistic of 4.41 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 555 stocks and an average market capitalization of at least \$1,454 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 25 bps/month with a t-statistics of 3.30. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-four exceed two, and for seventeen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas

measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 21-37bps/month. The lowest return, (21 bps/month), is achieved from the quintile sort using cap breakpoints and value-weighted portfolios, and has an associated t-statistic of 2.83. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the RDA trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-four cases.

Table 3 provides direct tests for the role size plays in the RDA strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and RDA, as well as average returns and alphas for long/short trading RDA strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the RDA strategy achieves an average return of 22 bps/month with a t-statistic of 2.40. Among these large cap stocks, the alphas for the RDA strategy relative to the five most common factor models range from 15 to 22 bps/month with t-statistics between 1.60 and 2.38.

5 How does RDA perform relative to the zoo?

Figure 2 puts the performance of RDA in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212

documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the RDA strategy falls in the distribution. The RDA strategy’s gross (net) Sharpe ratio of 0.55 (0.49) is greater than 93% (98%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the RDA strategy (red line).² Ignoring trading costs, a \$1 invested in the RDA strategy would have yielded \$8.50 which ranks the RDA strategy in the top 2% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the RDA strategy would have yielded \$6.25 which ranks the RDA strategy in the top 1% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the RDA relative to those. Panel A shows that the RDA strategy gross alphas fall between the 66 and 73 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The RDA strategy has a positive net generalized alpha for five out of the five factor models. In these cases RDA ranks between the 82 and 89 percentiles in terms of how much it could have expanded the achievable investment frontier.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does RDA add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of RDA with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price RDA or at least to weaken the power RDA has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of RDA conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RDA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RDA}RDA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{RDA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on RDA. Stocks are finally grouped into five RDA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

RDA trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on RDA and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the RDA signal in these Fama-MacBeth regressions exceed 1.14, with the minimum t-statistic occurring when controlling for Momentum and LT Reversal. Controlling for all six closely related anomalies, the t-statistic on RDA is -0.86.

Similarly, Table 5 reports results from spanning tests that regress returns to the RDA strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the RDA strategy earns alphas that range from 16-26bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.12, which is achieved when controlling for Momentum and LT Reversal. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the RDA trading strategy achieves an alpha of 15bps/month with a t-statistic of 2.10.

7 Does RDA add relative to the whole zoo?

Finally, we can ask how much adding RDA to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 154 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 154 anomalies augmented with the RDA signal.⁴ We consider

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capital-

one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 154-anomaly combination strategy grows to \$2560.30, while \$1 investment in the combination strategy that includes RDA grows to \$3096.43.

8 Conclusion

This study provides compelling evidence that Revenue Dilution Avoidance (RDA) represents a robust and economically significant predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that RDA-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for established risk factors and related anomalies.

The key findings reveal that a value-weighted long/short strategy based on RDA delivers an annualized Sharpe ratio of 0.55 gross (0.49 net), indicating strong performance even after accounting for transaction costs. More importantly, the strategy’s ability to generate significant alpha relative to the Fama-French five-factor model plus momentum (23 bps/month gross with t-statistic of 2.98) suggests that RDA captures a distinct dimension of expected returns not explained by conventional risk factors. The persistence of alpha (15 bps/month with t-statistic of 2.10) even after controlling for six closely related strategies—including various share issuance measures, payout yield, and growth metrics—further underscores the incremental information content of RDA.

ization on CRSP in the period for which RDA is available.

From a practical perspective, these results have important implications for both asset pricing theory and investment practice. The economic significance and statistical robustness of RDA suggest that investors' aversion to revenue dilution represents a material consideration in equity valuation that has been underappreciated in the existing literature. For practitioners, the net Sharpe ratio of 0.49 indicates that RDA-based strategies remain profitable after realistic implementation costs, making them potentially valuable additions to quantitative investment processes.

Several limitations of this study warrant consideration. First, while we employ the Novy-Marx and Velikov (2023) protocol to ensure robustness, the analysis is confined to U.S. equity markets, and the generalizability of RDA's predictive power to international markets remains unexplored. Second, the economic mechanisms underlying the RDA effect require further theoretical development to fully understand why markets appear to systematically misprice firms based on their revenue dilution characteristics.

Future research should pursue several promising directions. Investigating the performance of RDA in international equity markets would provide valuable out-of-sample validation and insights into whether the effect is driven by U.S.-specific institutional features. Additionally, examining the interaction between RDA and corporate events such as mergers, acquisitions, and restructurings could shed light on the economic channels through which revenue dilution affects firm value. Finally, exploring time-variation in the RDA premium and its relationship to macroeconomic conditions or market sentiment could enhance our understanding of when and why this signal is most effective. Such investigations would not only advance our theoretical understanding of asset pricing but also improve the practical implementation of RDA-based investment strategies.

Figure 1: Times series of RDA percentiles and coverage. This figure plots descriptive statistics for RDA. Panel A shows cross-sectional percentiles of RDA over the sample. Panel B plots the monthly coverage of RDA relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on RDA. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the RDA strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Decile	NYSE	VW	0.30 [3.32]	0.29 [3.19]	0.25 [2.78]	0.21 [2.41]	0.22 [2.41]	0.19 [2.15]

Table 3: Conditional sort on size and RDA

This table presents results for conditional double sorts on size and RDA. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on RDA. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high RDA and short stocks with low RDA. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 1963Q6 to 2024Q6.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	RDA Quintiles					RDA Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}	
	(1)	0.43 [1.67]	0.80 [3.12]	0.87 [3.51]	0.96 [3.92]	1.05 [4.61]	0.65 [7.02]	0.70 [7.63]	0.64 [7.32]	0.60 [6.67]	0.47 [5.61]	0.44 [5.20]
	(2)	0.55 [2.40]	0.82 [3.48]	0.82 [3.48]	0.97 [4.32]	0.91 [4.31]	0.36 [4.31]	0.42 [4.99]	0.33 [4.16]	0.31 [3.79]	0.22 [2.74]	0.21 [2.58]
	(3)	0.50 [2.48]	0.68 [3.17]	0.80 [3.67]	0.79 [3.87]	0.97 [5.07]	0.48 [5.96]	0.51 [6.32]	0.46 [5.75]	0.43 [5.25]	0.37 [4.63]	0.35 [4.32]
	(4)	0.46 [2.49]	0.64 [3.17]	0.83 [4.11]	0.76 [4.08]	0.80 [4.41]	0.34 [4.28]	0.36 [4.52]	0.29 [3.82]	0.29 [3.70]	0.10 [1.42]	0.12 [1.61]
	(5)	0.47 [2.90]	0.48 [2.69]	0.50 [2.86]	0.58 [3.52]	0.68 [4.34]	0.22 [2.40]	0.22 [2.38]	0.21 [2.26]	0.17 [1.82]	0.18 [1.91]	0.15 [1.60]
Panel B: Portfolio average number of firms and market capitalization												
Size quintiles	RDA Quintiles					RDA Quintiles						
	Average n					Average market capitalization (\$10 ⁶)						
	(L)	(2)	(3)	(4)	(H)	(L)	(2)	(3)	(4)	(H)		
	(1)	374	375	373	372	366	31	33	38	29	28	
	(2)	108	106	107	107	105	56	55	56	55	55	
	(3)	78	77	77	77	77	97	95	97	99	99	
	(4)	65	65	65	65	65	202	207	213	211	217	
(5)	60	60	60	60	60	1452	1425	1680	1643	1946		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the RDA with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the RDA trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with RDA. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of RDA conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{RDA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{RDA} RDA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{RDA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on RDA. Stocks are finally grouped into five RDA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted RDA trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on RDA. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{RDA}RDA_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Intercept	0.13 [6.11]	0.13 [6.47]	0.12 [5.44]	0.17 [6.93]	0.13 [5.81]	0.41 [1.20]	0.12 [2.82]
RDA	0.32 [4.73]	0.27 [3.58]	0.29 [3.64]	0.36 [5.14]	0.40 [5.72]	0.24 [1.14]	-0.24 [-0.86]

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the RDA trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{RDA} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Share issuance (1 year), Share issuance (5 year), Net Payout Yield, Growth in book equity, Change in equity to assets, Momentum and LT Reversal. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196306 to 202406.

Intercept	0.22 [2.91]	0.16 [2.12]	0.26 [3.44]	0.22 [2.91]	0.23 [3.01]	0.21 [2.77]	0.15 [2.10]

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 154 anomalies. The red solid lines indicate combination trading strategies that utilize the 154 anomalies as well as RDA. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
