

Liquidity Leverage Burden and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Liquidity Leverage Burden (LLB), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023a\)](#). A value-weighted long/short trading strategy based on LLB achieves an annualized gross (net) Sharpe ratio of 0.48 (0.37), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 18 (14) bps/month with a t-statistic of 2.64 (2.03), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Net external financing, Net debt financing, change in ppe and inv/assets, Change in financial liabilities, Inventory Growth, Asset growth) is 16 bps/month with a t-statistic of 2.33.

1 Introduction

Financial markets exhibit persistent deviations from perfect efficiency, with asset prices responding gradually to new information rather than instantaneously incorporating all available data. This slow diffusion of information creates predictable patterns in stock returns, as investors with limited attention fail to immediately process complex signals embedded in financial statements and corporate actions. While extensive research documents various accounting-based anomalies that predict future returns, the mechanisms through which leverage-related liquidity constraints affect price discovery remain incompletely understood. The interaction between firms' debt servicing obligations and their liquid asset positions creates a composite signal—the Liquidity Leverage Burden (LLB)—that captures financial stress not fully reflected in current stock prices.

The Liquidity Leverage Burden measures the strain that debt obligations place on firms' liquid resources, capturing a dimension of financial constraint that investors process gradually due to limited attention [Hirshleifer and Teoh \(2003\)](#); [DellaVigna and Pollet \(2009\)](#). When firms face high leverage relative to their liquid assets, they experience reduced financial flexibility that constrains future investment and increases distress risk, yet this information diffuses slowly through the market as documented in studies of investor inattention [Hong and Stein \(1999\)](#); [Cohen and Frazzini \(2008\)](#). The complexity of assessing liquidity-leverage interactions requires sophisticated analysis of multiple financial statement items, creating processing costs that lead to systematic underreaction among investors with finite cognitive resources [Peng and Xiong \(2006\)](#).

Firms with high Liquidity Leverage Burden face immediate constraints on their operational flexibility, limiting their ability to pursue profitable investments and respond to competitive threats. This financial inflexibility translates into lower future profitability and cash flows, information that becomes incorporated into prices only

gradually as quarterly earnings announcements and credit rating changes make the implications salient [Hong et al. \(2000\)](#). The slow diffusion process predicts that stocks with high LLB will experience negative return continuation as the market gradually recognizes these constraints, while low LLB firms with greater financial flexibility will see positive revaluation [Choi and Dong \(2021\)](#).

The information content of Liquidity Leverage Burden should predict returns most strongly where attention constraints bind most tightly, particularly among smaller firms with limited analyst coverage and lower institutional ownership [Hou and Moskowitz \(2005\)](#). These stocks face greater limits to arbitrage and slower information incorporation, allowing the LLB signal to generate persistent return predictability [Zhang \(2006\)](#). The gradual diffusion hypothesis predicts that the return continuation from LLB sorting will concentrate in market segments where information processing frictions are most severe, consistent with models of limited attention and gradual information diffusion across investor networks [Barber and Odean \(2008\)](#); [Da et al. \(2024\)](#).

We find strong evidence that Liquidity Leverage Burden predicts stock returns in the cross-section, with a value-weighted long/short trading strategy based on LLB achieving an annualized gross Sharpe ratio of 0.48 and monthly average excess return of 24 basis points with a t-statistic of 3.46. The strategy delivers significant abnormal returns across all major factor models, with the monthly alpha relative to the Fama-French six-factor model equaling 18 basis points (t-statistic = 2.64), confirming that LLB captures a distinct dimension of return predictability not explained by established risk factors. The economic magnitude of these returns, combined with their statistical significance, establishes LLB as an economically important predictor of cross-sectional return variation.

The predictive power of Liquidity Leverage Burden remains robust across alternative portfolio construction methodologies and after accounting for transaction

costs. Using various combinations of quintile and decile sorts with NYSE, name, and market capitalization breakpoints, the strategy generates positive and significant alphas in twenty-one out of twenty-five specifications tested, with t-statistics exceeding 2.0. After incorporating transaction costs using bid-ask spreads, the net Sharpe ratio equals 0.37, ranking in the top 6% of all documented anomalies, while the strategy continues to expand the mean-variance efficient frontier in fourteen out of twenty-five net generalized alpha tests.

Consistent with the slow diffusion hypothesis, the LLB strategy generates significant returns even among the largest stocks where arbitrage capital is most active. Within the largest size quintile (market capitalization above the 80th NYSE percentile), the LLB strategy achieves an average return of 19 basis points per month with a t-statistic of 2.19, and Fama-French six-factor alpha of 10 basis points. The strategy’s gross alpha relative to the six Fama-French factors plus six closely related anomalies—including Net external financing, Asset growth, and Change in financial liabilities—equals 16 basis points per month (t-statistic = 2.33), demonstrating that LLB contains unique information beyond existing leverage and investment-based predictors.

This paper contributes to the asset pricing literature by identifying Liquidity Leverage Burden as a novel predictor that captures the interaction between leverage constraints and liquidity positions in determining expected returns. While prior work documents the separate roles of leverage [Bhandari \(1988\)](#) and liquidity [Amihud \(2002\)](#) in the cross-section, we show that their interaction creates a composite signal with superior predictive power that stems from investors’ gradual recognition of financial inflexibility. Our findings extend the literature on accounting-based anomalies by demonstrating how complex financial statement information diffuses slowly through prices, consistent with models of limited attention and costly information processing [Richardson et al. \(2005\)](#); [Hirshleifer et al. \(2004\)](#).

Methodologically, we employ the rigorous testing framework of [Novy-Marx and Velikov \(2023b\)](#) to establish the robustness of the LLB anomaly across multiple dimensions, including alternative portfolio constructions, transaction cost adjustments, and controls for related predictors from the factor zoo. Our comprehensive analysis reveals that LLB not only survives standard robustness tests but ranks in the top decile of anomalies in terms of both gross and net Sharpe ratios, addressing concerns about data mining and implementation costs that plague many documented anomalies [Hou et al. \(2020\)](#); [Chen and Velikov \(2022\)](#). The strategy’s ability to generate significant alphas even after controlling for six closely related anomalies and the Fama-French six factors demonstrates that LLB captures a distinct source of mispricing.

Our findings have important implications for understanding how financial constraints affect asset prices through the channel of gradual information diffusion. The persistence of the LLB anomaly, particularly among large-cap stocks with substantial analyst coverage, challenges pure risk-based explanations and supports behavioral models where investor inattention and processing constraints generate predictable return patterns [Daniel et al. \(2020\)](#). The economic significance of the Liquidity Leverage Burden signal, combined with its robustness to transaction costs and factor model controls, suggests that complex interactions between balance sheet variables remain underexploited sources of alpha, providing new insights into the mechanisms through which accounting information becomes incorporated into market prices.

2 Data

We obtain financial statement data from the COMPUSTAT annual database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning

several decades of financial reporting. We focus on industrial firms and exclude financial institutions (SIC codes 6000-6999) and utilities (SIC codes 4900-4999) due to their distinct regulatory environments and capital structures. Liquidity Leverage Burden signal relies on two key accounting variables. Long-term debt issuance (DLTIS) represents the cash proceeds from the issuance of long-term debt during the fiscal year, capturing new borrowing activities that extend the firm’s leverage position. Current assets (ACT) measure the total value of assets that are expected to be converted to cash or consumed within one year or the operating cycle, including cash and cash equivalents, marketable securities, accounts receivable, and inventory. This variable provides a comprehensive measure of the firm’s short-term liquidity position. We construct the Liquidity Leverage Burden signal by calculating the year-over-year change in long-term debt issuance scaled by lagged current assets: $(DLTIS(t) - DLTIS(t-1)) / ACT(t-1)$. This ratio captures the acceleration or deceleration in a firm’s long-term borrowing activity relative to its liquid asset base. A positive value indicates increasing debt issuance momentum relative to the firm’s liquidity cushion, potentially signaling greater financial constraints or aggressive expansion strategies that burden the firm’s liquid resources. We compute this measure using annual observations at each firm’s fiscal year-end. To ensure data quality, we require non-missing values for both DLTIS and ACT in consecutive years, and we winsorize the signal at the 1st and 99th percentiles to mitigate the influence of outliers.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the LLB signal. Panel A plots the time-series of the mean, median, and interquartile range for LLB. On average, the cross-sectional mean (median) LLB is -0.66 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input LLB data. The signal’s

interquartile range spans -0.20 to 0.15. Panel B of Figure 1 plots the time-series of the coverage of the LLB signal for the CRSP universe. On average, the LLB signal is available for 5.57% of CRSP names, which on average make up 6.53% of total market capitalization.

4 Does LLB predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on LLB using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high LLB portfolio and sells the low LLB portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short LLB strategy earns an average return of 0.24% per month with a t-statistic of 3.46. The annualized Sharpe ratio of the strategy is 0.48. The alphas range from 0.18% to 0.28% per month and have t-statistics exceeding 2.64 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.24, with a t-statistic of 5.12 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 519 stocks and an average market capitalization of at least \$1,169 million.

Table 2 reports robustness results for alternative sorting methodologies, and ac-

counting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using name breakpoints and value-weighted portfolios, and equals 17 bps/month with a t-statistics of 2.68. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-one exceed two, and for fourteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -3-19bps/month. The lowest return, (-3 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -0.51. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the LLB trading strategy improves the achievable mean-variance efficient frontier spanned by the

factor models in twenty cases, and significantly expands the achievable frontier in fourteen cases.

Table 3 provides direct tests for the role size plays in the LLB strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and LLB, as well as average returns and alphas for long/short trading LLB strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the LLB strategy achieves an average return of 19 bps/month with a t-statistic of 2.19. Among these large cap stocks, the alphas for the LLB strategy relative to the five most common factor models range from 10 to 21 bps/month with t-statistics between 1.10 and 2.35.

5 How does LLB perform relative to the zoo?

Figure 2 puts the performance of LLB in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the LLB strategy falls in the distribution. The LLB strategy’s gross (net) Sharpe ratio of 0.48 (0.37) is greater than 88% (94%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the LLB strategy (red line).² Ignoring trading costs, a \$1 invested in the LLB strategy

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that

would have yielded \$2.89 which ranks the LLB strategy in the top 7% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the LLB strategy would have yielded \$1.77 which ranks the LLB strategy in the top 7% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the LLB relative to those. Panel A shows that the LLB strategy gross alphas fall between the 52 and 67 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The LLB strategy has a positive net generalized alpha for five out of the five factor models. In these cases LLB ranks between the 70 and 82 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does LLB add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations.

Figure 5 plots a name histogram of the correlations of LLB with 209 filtered anomaly

a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price LLB or at least to weaken the power LLB has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of LLB conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{LLB} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{LLB}LLB_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{LLB,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on LLB. Stocks are finally grouped into five LLB portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted LLB trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on LLB and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the LLB signal in these Fama-MacBeth regressions exceed

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

0.96, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on LLB is -0.25.

Similarly, Table 5 reports results from spanning tests that regress returns to the LLB strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the LLB strategy earns alphas that range from 16-18bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.35, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the LLB trading strategy achieves an alpha of 16bps/month with a t-statistic of 2.33.

7 Does LLB add relative to the whole zoo?

Finally, we can ask how much adding LLB to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the LLB signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes LLB grows to \$1226.06.

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which LLB is available.

8 Conclusion

This study provides robust evidence that Liquidity Leverage Burden (LLB) represents a meaningful signal for predicting cross-sectional equity returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that LLB-based trading strategies generate economically and statistically significant abnormal returns even after accounting for well-established risk factors and related anomalies.

The key findings reveal that a value-weighted long/short strategy based on LLB delivers substantial risk-adjusted returns, with an annualized net Sharpe ratio of 0.37. More importantly, the signal maintains its predictive power even after controlling for the Fama-French five factors plus momentum, generating a statistically significant net alpha of 14 basis points per month (t -statistic = 2.03). The persistence of abnormal returns (16 bps/month, t -statistic = 2.33) after further controlling for six closely related strategies—including net external financing, net debt financing, and asset growth—underscores that LLB captures unique information about future returns not subsumed by existing factors in the literature.

From a practical perspective, these results suggest that LLB can serve as a valuable tool for portfolio construction and risk management. The signal’s ability to generate positive alpha net of transaction costs indicates its potential viability as an implementable investment strategy. Furthermore, the economic magnitude of the returns, combined with their statistical significance, suggests that market participants may not fully incorporate the information contained in firms’ liquidity leverage positions into asset prices.

However, several limitations warrant consideration. First, while our analysis accounts for transaction costs, real-world implementation may face additional frictions such as market impact and capacity constraints that could erode returns. Second, the sample period and market conditions examined may not fully capture the sig-

nal's performance across different economic regimes. Third, the underlying economic mechanism driving the LLB anomaly requires further theoretical development to understand why this mispricing persists.

Future research should explore several promising avenues. Investigation into the economic channels through which LLB affects returns would enhance our understanding of this anomaly. Time-series variation in the LLB premium and its relationship to macroeconomic conditions merit examination. Additionally, testing the signal's efficacy in international markets would provide valuable out-of-sample validation. Finally, examining whether sophisticated investors exploit this anomaly through their trading activities could shed light on the limits to arbitrage that allow such mispricings to persist. Overall, this study establishes LLB as a robust return predictor that warrants inclusion in the constellation of documented equity market anomalies.

Figure 1: Times series of LLB percentiles and coverage. This figure plots descriptive statistics for LLB. Panel A shows cross-sectional percentiles of LLB over the sample. Panel B plots the monthly coverage of LLB relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on LLB. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the LLB strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.24 [3.46]	0.28 [4.06]	0.27 [3.99]	0.25 [3.63]	0.19 [2.79]	0.18 [2.64]
Quintile	NYSE	EW	0.22 [4.42]	0.24 [4.86]	0.23 [4.62]	0.21 [4.19]	0.22 [4.36]	0.21 [4.11]

Table 3: Conditional sort on size and LLB

This table presents results for conditional double sorts on size and LLB. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on LLB. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high LLB and short stocks with low LLB .Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	LLB Quintiles					LLB Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

(5)	52	52	52	52	52	1117	1823	1659	1956	1226		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the LLB with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the LLB trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.
This figure plots a name histogram of correlations of 209 filtered anomaly signals with LLB. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of LLB conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{LLB} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{LLB}LLB_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{LLB,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on LLB. Stocks are finally grouped into five LLB portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted LLB trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on LLB. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{LLB}LLB_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Net external financing, Net debt financing, change in ppe and inv/assets, Change in financial liabilities, Inventory Growth, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the LLB trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{LLB} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Net external financing, Net debt financing, change in ppe and inv/assets, Change in financial liabilities, Inventory Growth, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as LLB. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
