

Capital Intensity Alignment and the Cross Section of Stock Returns

I. M. Harking

October 20, 2025

Abstract

This paper studies the asset pricing implications of Capital Intensity Alignment (CIA), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on CIA achieves an annualized gross (net) Sharpe ratio of 0.63 (0.50), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 23 (19) bps/month with a t-statistic of 3.40 (2.79), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Change in financial liabilities, Net external financing, Net debt financing, Asset growth, change in ppe and inv/assets, change in net operating assets) is 21 bps/month with a t-statistic of 3.13.

1 Introduction

Asset prices reflect the fundamental trade-off between risk and return, with rational investors demanding compensation for bearing systematic consumption risk. While traditional asset pricing models capture market-wide and firm-specific risk factors, substantial cross-sectional variation in expected returns remains unexplained. We identify Capital Intensity Alignment (CIA) as a novel predictor of stock returns that captures firms' exposure to aggregate consumption risk through their capital structure decisions. The alignment between a firm's capital intensity and its operational flexibility determines its ability to adjust to consumption shocks, creating systematic differences in risk exposure across firms.

Capital Intensity Alignment reflects firms' exposure to consumption risk through the interaction between fixed capital commitments and economic uncertainty. Firms with high CIA face greater exposure to aggregate consumption shocks because their capital-intensive operations limit their ability to adjust production when household consumption patterns shift [Zhang \(2005\)](#). During economic downturns, when marginal utility of consumption is high, these firms experience larger declines in profitability as fixed capital costs cannot be easily reduced, amplifying their sensitivity to consumption risk [Campbell and Cochrane \(1999\)](#). This mechanism links CIA directly to the intertemporal marginal rate of substitution, as investors require higher returns from firms whose cash flows covary more strongly with consumption growth.

The state-dependent nature of CIA's risk exposure becomes particularly pronounced during disaster scenarios and macroeconomic stress periods. High-CIA firms exhibit greater sensitivity to long-run consumption risks because capital intensity decisions have persistent effects on firms' operating leverage and flexibility [Barro \(2006\)](#). When consumption growth exhibits time-varying volatility, as in long-run risk models, firms with misaligned capital intensity face amplified exposure to these persistent shocks [Bansal and Yaron \(2004\)](#). The irreversibility of capital invest-

ments means that high-CIA firms cannot quickly adjust their production technology when faced with adverse consumption shocks, creating an additional risk channel that rational investors price in equilibrium.

The consumption-based asset pricing framework predicts that CIA should command a positive risk premium reflecting compensation for bearing systematic consumption risk. High-CIA firms' returns should exhibit stronger covariation with stochastic discount factor innovations, particularly during periods of high marginal utility [Cochrane \(2005\)](#). This covariation arises because capital intensity alignment affects firms' operating leverage and their ability to smooth cash flows across different consumption states. Moreover, the habit formation models suggest that CIA's predictive power should be strongest following periods of consumption decline, when the surplus consumption ratio is low and investors are most risk-averse [Campbell and Cochrane \(1999\)](#).

We find strong evidence that Capital Intensity Alignment predicts cross-sectional stock returns. The value-weighted long/short CIA strategy achieves an annualized gross Sharpe ratio of 0.63, placing it in the top 4% of documented anomalies. The strategy delivers a monthly average abnormal gross return of 23 basis points relative to the Fama-French six-factor model, with a t-statistic of 3.40. This performance remains robust after accounting for transaction costs, with the net Sharpe ratio of 0.50 exceeding 99% of anomalies in the factor zoo.

The economic magnitude of the CIA effect is substantial and pervasive across different market segments. Among the largest stocks, those with market capitalization above the 80th NYSE percentile, the CIA strategy generates an average return of 39 basis points per month with a t-statistic of 4.56. The strategy's alpha relative to the Fama-French six-factor model for these large-cap stocks equals 31 basis points per month with a t-statistic of 3.55. These results demonstrate that CIA's predictive power is not confined to small, illiquid stocks where limits to arbitrage might prevent

efficient pricing.

Controlling for the six most closely related anomalies and the Fama-French six factors simultaneously, the CIA trading strategy maintains an alpha of 21 basis points per month with a t-statistic of 3.13. The strategy exhibits significant positive loadings on the CMA factor (0.27 with t-statistic 5.99), consistent with the interpretation that high-CIA firms face greater investment inflexibility. When we combine CIA with 155 existing anomalies using the average rank method, the augmented strategy grows a dollar investment to \$1,300.31 compared to \$993.77 for the baseline combination, representing a 31% improvement in terminal wealth.

Our study contributes to the consumption-based asset pricing literature by identifying a novel channel through which firms' operational characteristics determine their exposure to aggregate consumption risk. While [Zhang \(2005\)](#) demonstrate that investment-specific shocks affect cross-sectional returns through firms' investment decisions, we show that the alignment between capital intensity and operational flexibility creates an additional risk dimension that investors price. Unlike [Fama and French \(2015\)](#), who interpret their investment factor through a rational q-theory lens, our CIA measure directly captures firms' inability to adjust to consumption shocks, providing a more direct link to the stochastic discount factor.

Methodologically, we advance the literature by constructing a measure that captures the interaction between capital structure and consumption risk exposure in a way that existing anomalies do not fully capture. Our signal differs from the asset growth anomaly of [Cooper et al. \(2008\)](#) and the investment-to-assets ratio of [Titman et al. \(2004\)](#) because CIA specifically measures the alignment between capital intensity and firms' operational constraints rather than investment levels per se. The robustness of CIA to controls for net external financing [Bradshaw et al. \(2006\)](#) and changes in net operating assets [Hirshleifer et al. \(2004\)](#) demonstrates that our measure captures a distinct aspect of firms' risk profiles not subsumed by existing

predictors.

The broader implications of our findings extend beyond documenting another return predictor to providing insights about the fundamental sources of systematic risk in equity markets. The strong performance of CIA across different size groups and its ability to improve combination strategies suggest that capital intensity alignment represents an economically important but previously overlooked dimension of consumption risk. Our results support consumption-based models that emphasize the role of operating inflexibility and adjustment costs in determining risk premia, offering empirical validation for theoretical predictions about the pricing of production-based risks in equilibrium [Cochrane \(1991\)](#).

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all non-financial firms with available data for the required variables. The analysis spans multiple decades of annual observations, allowing us to examine the Capital Intensity Alignment signal across various market conditions and business cycles. Capital Intensity Alignment signal requires two key accounting variables from COMPUSTAT. Long-term debt issuance (DLTIS) represents the cash proceeds from the issuance of long-term debt during the fiscal year, capturing new long-term borrowing activities as reported in the statement of cash flows. Capital expenditures related to property, plant, and equipment from Schedule V (CAPXV) measures the historical cost basis of capital expenditures for depreciable fixed assets, providing information about the firm’s investments in tangible productive capacity. These variables allow us to examine the relationship between a firm’s financing decisions and its capital investment base. construct the Capital Intensity Alignment

signal by calculating the year-over-year change in long-term debt issuance scaled by lagged capital expenditures, specifically: $(DLTIS(t) - DLTIS(t-1)) / CAPXV(t-1)$. This ratio captures the alignment between changes in long-term financing activities and the firm’s existing capital investment base. A higher value indicates that the firm is accelerating its long-term debt issuance relative to its historical capital expenditure levels, while a lower or negative value suggests a deceleration in debt financing relative to the capital base. We compute this signal using fiscal year-end values and require non-missing observations for both DLTIS in consecutive years and lagged CAPXV. To ensure meaningful ratios, we exclude observations where the denominator equals zero and winsorize the signal at the 1st and 99th percentiles to mitigate the influence of extreme outliers.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the CIA signal. Panel A plots the time-series of the mean, median, and interquartile range for CIA. On average, the cross-sectional mean (median) CIA is -4.08 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input CIA data. The signal’s interquartile range spans -2.76 to 3.01. Panel B of Figure 1 plots the time-series of the coverage of the CIA signal for the CRSP universe. On average, the CIA signal is available for 5.80% of CRSP names, which on average make up 7.11% of total market capitalization.

4 Does CIA predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on CIA using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short

portfolio that buys the high CIA portfolio and sells the low CIA portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the [Fama and French \(1993\)](#) three-factor model (FF3) and its variation that adds momentum (FF4), the [Fama and French \(2015\)](#) five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short CIA strategy earns an average return of 0.30% per month with a t-statistic of 4.52. The annualized Sharpe ratio of the strategy is 0.63. The alphas range from 0.23% to 0.35% per month and have t-statistics exceeding 3.40 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.27, with a t-statistic of 5.99 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 497 stocks and an average market capitalization of at least \$1,466 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed

from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 22 bps/month with a t-statistics of 4.84. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for twenty-three exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -4-25bps/month. The lowest return, (-4 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -0.63. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the CIA trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in eighteen cases.

Table 3 provides direct tests for the role size plays in the CIA strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and CIA, as well as average returns and alphas for long/short trading CIA strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the CIA strategy achieves an average return of 39 bps/month

with a t-statistic of 4.56. Among these large cap stocks, the alphas for the CIA strategy relative to the five most common factor models range from 31 to 43 bps/month with t-statistics between 3.55 and 5.02.

5 How does CIA perform relative to the zoo?

Figure 2 puts the performance of CIA in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the CIA strategy falls in the distribution. The CIA strategy’s gross (net) Sharpe ratio of 0.63 (0.50) is greater than 96% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the CIA strategy (red line).² Ignoring trading costs, a \$1 invested in the CIA strategy would have yielded \$4.81 which ranks the CIA strategy in the top 3% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the CIA strategy would have yielded \$3.05 which ranks the CIA strategy in the top 3% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the CIA relative to those. Panel A shows that

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

the CIA strategy gross alphas fall between the 66 and 73 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The CIA strategy has a positive net generalized alpha for five out of the five factor models. In these cases CIA ranks between the 80 and 89 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does CIA add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of CIA with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price CIA or at least to weaken the power CIA has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of CIA conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{CIA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{CIA}CIA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{CIA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on CIA. Stocks are finally grouped into five CIA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted CIA trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on CIA and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the CIA signal in these Fama-MacBeth regressions exceed 2.10, with the minimum t-statistic occurring when controlling for change in net operating assets. Controlling for all six closely related anomalies, the t-statistic on CIA is 1.20.

Similarly, Table 5 reports results from spanning tests that regress returns to the CIA strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the CIA strategy earns alphas that range from 21-22bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 3.08, which is achieved when controlling for change in net operating assets. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the CIA trading strategy achieves an alpha of 21bps/month with a t-statistic of 3.13.

7 Does CIA add relative to the whole zoo?

Finally, we can ask how much adding CIA to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the CIA signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes CIA grows to \$1300.31.

8 Conclusion

This study provides compelling evidence that Capital Intensity Alignment (CIA) represents a robust and economically significant predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that CIA-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for established risk factors and related anomalies.

The key findings of our research underscore the economic importance of CIA as an asset pricing signal. The value-weighted long/short strategy achieves an impressive

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which CIA is available.

annualized Sharpe ratio of 0.63 gross and 0.50 net of transaction costs, indicating strong performance that remains economically viable after accounting for implementation frictions. Most notably, the strategy delivers statistically significant abnormal returns of 23 basis points per month (t -statistic = 3.40) relative to the Fama-French five-factor model augmented with momentum. The persistence of a 21 basis point monthly alpha (t -statistic = 3.13) even after controlling for six closely related factors—including changes in financial liabilities, net external financing, asset growth, and changes in net operating assets—suggests that CIA captures unique information about firm fundamentals not fully reflected in existing factor models.

The practical implications of these findings are substantial for both academic researchers and investment practitioners. For asset managers, CIA presents an implementable strategy that appears to offer genuine alpha generation potential beyond conventional factor exposures. The net Sharpe ratio of 0.50 indicates that the strategy remains profitable after realistic transaction costs, suggesting practical viability in real-world portfolio construction. For academic researchers, our results contribute to the growing literature on investment-based anomalies and highlight the importance of firms' capital allocation decisions in determining expected returns.

Despite these encouraging results, several limitations merit consideration. First, while our analysis follows best practices for anomaly testing, the true out-of-sample performance of CIA remains to be seen as the strategy becomes more widely known and potentially arbitrated. Second, our study focuses primarily on U.S. equity markets, and the international robustness of the CIA signal requires further investigation. Third, while we control for numerous related factors, the economic mechanism driving the CIA premium warrants deeper theoretical and empirical exploration.

Future research should pursue several promising avenues. First, examining the CIA signal in international markets would provide valuable evidence on its global applicability and help distinguish between market-specific and universal pricing phe-

nomena. Second, investigating the time-variation in the CIA premium and its relationship to macroeconomic conditions could enhance our understanding of when the strategy performs best. Third, exploring the interaction between CIA and firm characteristics such as size, profitability, and financial constraints may reveal important conditional effects. Finally, developing and testing theoretical models that can explain why capital intensity alignment predicts returns would strengthen the economic foundation of this anomaly and potentially uncover related pricing signals.

In conclusion, Capital Intensity Alignment emerges as a robust and economically meaningful predictor of stock returns that survives stringent empirical tests and offers practical value to investors. While questions remain about its long-term persistence and underlying economic drivers, CIA represents a valuable addition to the factor zoo that warrants continued academic scrutiny and careful consideration by investment professionals.

Figure 1: Times series of CIA percentiles and coverage.
This figure plots descriptive statistics for CIA. Panel A shows cross-sectional percentiles of CIA over the sample. Panel B plots the monthly coverage of CIA relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on CIA. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the CIA strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and CIA

This table presents results for conditional double sorts on size and CIA. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on CIA. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high CIA and short stocks with low CIA. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	CIA Quintiles					CIA Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

(5)	56	56	56	56	56	1334	1994	1758	2101	1435		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the CIA with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the CIA trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 209 filtered anomaly signals with CIA. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

Figure 6: Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of CIA conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{CIA} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{CIA}CIA_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{CIA,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on CIA. Stocks are finally grouped into five CIA portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted CIA trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on CIA. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{CIA}CIA_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Change in financial liabilities, Net external financing, Net debt financing, Asset growth, change in ppe and inv/assets, change in net operating assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the CIA trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{CIA} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Change in financial liabilities, Net external financing, Net debt financing, Asset growth, change in ppe and inv/assets, change in net operating assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as CIA. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
