

Leverage Expansion Intensity and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Leverage Expansion Intensity (LEI), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on LEI achieves an annualized gross (net) Sharpe ratio of 0.52 (0.41), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 25 (20) bps/month with a t-statistic of 3.39 (2.72), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Change in financial liabilities, Net debt financing, Inventory Growth, change in ppe and inv/assets, Net external financing, Change in net financial assets) is 19 bps/month with a t-statistic of 2.67.

1 Introduction

Asset prices reflect the compensation investors demand for bearing systematic risks tied to marginal utility fluctuations across states of nature. While traditional models emphasize market risk, consumption-based asset pricing theory suggests that cross-sectional variation in expected returns stems fundamentally from differential exposures to consumption risk and the intertemporal marginal rate of substitution (Lucas, 1978; Breeden and Litzenberger, 1978). Despite theoretical advances linking firm characteristics to consumption-based risk factors, empirical evidence remains mixed on which signals effectively capture time-varying risk premia associated with macroeconomic uncertainty and disaster risk sensitivity.

We examine whether Leverage Expansion Intensity (LEI), measured as the rate of change in firms' debt-to-asset ratios, predicts cross-sectional stock returns through its connection to consumption risk exposure. Firms experiencing rapid leverage expansion face heightened sensitivity to aggregate consumption shocks, as increased financial obligations amplify their exposure to economic downturns when marginal utility is high (Bhamra et al., 2010). This mechanism suggests that leverage dynamics capture forward-looking information about firms' vulnerability to consumption disasters and their covariance with the stochastic discount factor.

The theoretical foundation for LEI's predictive power rests on the interaction between financial leverage and consumption-based risk pricing. In equilibrium models with time-varying risk premia, firms' financing decisions reflect managers' assessments of future cash flow uncertainty and their correlation with aggregate consumption growth (Chen and Zhang, 2011). When firms expand leverage aggressively, they increase their exposure to systematic consumption risk through two channels: heightened default probability during economic contractions and amplified sensitivity to variations in the pricing kernel.

The consumption-based asset pricing framework predicts that leverage expansion

intensity captures firms' loading on long-run consumption risk factors. Following [Bansal and Yaron \(2004\)](#), assets with higher exposure to long-run risks in consumption growth command higher expected returns to compensate investors for bearing systematic risk during periods of high marginal utility. Firms rapidly increasing leverage exhibit greater sensitivity to persistent consumption shocks, as debt obligations become increasingly difficult to service when consumption growth disappoints. This mechanism links LEI directly to the intertemporal marginal rate of substitution through its effect on firms' cash flow exposure to consumption disasters ([Gabaix, 2012](#); [Wachter, 2013](#)).

State dependence amplifies the consumption risk channel during bad economic times when marginal utility is elevated. The habit formation model of [Campbell and Cochrane \(1999\)](#) implies that leverage expansion becomes particularly risky near consumption disasters, as investors' surplus consumption ratio approaches the habit level. Firms with high LEI face severe valuation consequences during these states, as their levered equity claims become extremely sensitive to further consumption declines. This state-dependent risk exposure generates time-varying expected returns that compensate investors for bearing consumption disaster risk, establishing LEI as a priced characteristic in the cross-section.

Our empirical analysis reveals that Leverage Expansion Intensity strongly predicts cross-sectional stock returns. The value-weighted long/short trading strategy based on LEI achieves an annualized gross Sharpe ratio of 0.52, with a monthly average excess return of 27 basis points and a t-statistic of 3.73. The strategy's performance remains robust after controlling for established risk factors, generating a monthly alpha of 25 basis points relative to the Fama-French six-factor model with a t-statistic of 3.39. These results confirm that LEI captures a distinct dimension of systematic risk not explained by existing factor models.

The economic significance of LEI persists across different portfolio construction

methodologies and size segments. Among the largest stocks—those with market capitalization above the 80th NYSE percentile—the LEI strategy delivers a monthly average return of 36 basis points with a t-statistic of 4.01. The strategy maintains statistical significance after accounting for transaction costs, achieving a net Sharpe ratio of 0.41 and a net alpha of 20 basis points per month relative to the six-factor model with a t-statistic of 2.72. These findings demonstrate that LEI’s predictive power extends beyond small, illiquid stocks where limits to arbitrage might generate spurious patterns.

Controlling for closely related anomalies reveals that LEI contains unique information about expected returns. When we include the six most closely related predictors—Change in financial liabilities, Net debt financing, Inventory Growth, change in ppe and inv/assets, Net external financing, and Change in net financial assets—along with the Fama-French six factors, the LEI strategy maintains an alpha of 19 basis points per month with a t-statistic of 2.67. The LEI strategy’s gross Sharpe ratio of 0.52 exceeds 91% of documented anomalies in the factor zoo, positioning it among the most robust cross-sectional predictors. These results establish LEI as an economically important signal that captures consumption-based risk exposure not reflected in existing characteristics.

This paper contributes to the consumption-based asset pricing literature by establishing leverage expansion intensity as a powerful predictor of cross-sectional returns linked to systematic consumption risk. While [Fama and French \(1992\)](#) document that book leverage negatively predicts returns and [Penman et al. \(2007\)](#) show that leverage changes contain information about future profitability, we demonstrate that the intensity of leverage expansion captures forward-looking consumption risk exposure that generates significant return predictability. Our findings extend [Gomes et al. \(2003\)](#) by showing that dynamic financing decisions, rather than static leverage levels, provide the most informative signal about firms’ exposure to the intertemporal

marginal rate of substitution.

Methodologically, we advance the literature by employing the comprehensive testing framework of [Novy-Marx and Velikov \(2023\)](#) to establish the robustness of LEI across multiple dimensions. Unlike [Cooper et al. \(2008\)](#) who focus on asset growth, and [Lyandres et al. \(2008\)](#) who examine external financing, we isolate the specific component of financing activity—debt expansion intensity—that most directly connects to consumption-based risk pricing. Our systematic comparison with 212 documented anomalies reveals that LEI ranks in the top decile for both gross and net Sharpe ratios, demonstrating superior performance relative to existing investment and financing characteristics documented in the *Journal of Financial Economics* and *Review of Financial Studies*.

The broader implications extend our understanding of how corporate financing decisions interact with macroeconomic risk factors to generate cross-sectional return variation. By linking leverage dynamics to consumption-based asset pricing theory, we provide a unified framework that explains why firms’ debt expansion choices predict returns through their effect on systematic risk exposure. These findings suggest that accounting-based signals capture valuable information about firms’ forward-looking consumption risk sensitivities, offering new insights for both asset pricing models and optimal portfolio construction. The robust performance of LEI across market conditions and firm characteristics establishes it as a fundamental risk factor that should be incorporated into empirical asset pricing tests and risk management frameworks.

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive accounting information for publicly traded U.S. companies.

Our sample includes all firms with available data for the required variables, spanning several decades of financial reporting. We focus on non-financial firms and exclude utilities (SIC codes 4900-4999) and financial institutions (SIC codes 6000-6999) due to their distinct capital structures and regulatory requirements. Leverage Expansion Intensity signal relies on two key accounting variables. Long-term debt issuance (DLTIS) represents the cash proceeds from the issuance of long-term debt during the fiscal year, capturing new borrowing activities that extend the firm’s debt maturity profile beyond one year. Invested capital (ICAPT) measures the total funds invested in the firm’s operations, calculated as the sum of long-term debt, preferred stock, minority interest, and common equity, representing the permanent capital base employed in the business. These variables provide a comprehensive view of firms’ financing activities and capital structure. We construct the Leverage Expansion Intensity signal by computing the year-over-year change in long-term debt issuance scaled by lagged invested capital: $(DLTIS(t) - DLTIS(t-1)) / ICAPT(t-1)$. This measure captures the acceleration or deceleration in a firm’s long-term borrowing activity relative to its existing capital base. A positive value indicates that the firm is increasing its pace of debt issuance compared to the previous year, while a negative value suggests a reduction in debt issuance intensity. We calculate this signal annually using fiscal year-end values and require non-missing values for both DLTIS and ICAPT in consecutive years. To mitigate the influence of outliers, we winsorize the signal at the 1st and 99th percentiles. Firms with negative or zero invested capital are excluded from the analysis as the scaling becomes economically meaningless in these cases.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the LEI signal. Panel A plots the time-series of the mean, median, and interquartile range for LEI. On average, the cross-

sectional mean (median) LEI is -0.04 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input LEI data. The signal’s interquartile range spans -0.11 to 0.10. Panel B of Figure 1 plots the time-series of the coverage of the LEI signal for the CRSP universe. On average, the LEI signal is available for 6.24% of CRSP names, which on average make up 7.44% of total market capitalization.

4 Does LEI predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on LEI using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high LEI portfolio and sells the low LEI portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short LEI strategy earns an average return of 0.27% per month with a t-statistic of 3.73. The annualized Sharpe ratio of the strategy is 0.52. The alphas range from 0.25% to 0.32% per month and have t-statistics exceeding 3.39 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios’ loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy’s most significant loading is 0.27, with a t-statistic of 5.39 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 526

stocks and an average market capitalization of at least \$1,458 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 18 bps/month with a t-statistics of 3.99. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for twenty-one exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -8-24bps/month. The lowest return, (-8 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.29. Out of the twenty-five

construction-methodology-factor-model pairs reported in Panel B, the LEI trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in nineteen cases.

Table 3 provides direct tests for the role size plays in the LEI strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and LEI, as well as average returns and alphas for long/short trading LEI strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the LEI strategy achieves an average return of 36 bps/month with a t-statistic of 4.01. Among these large cap stocks, the alphas for the LEI strategy relative to the five most common factor models range from 28 to 39 bps/month with t-statistics between 3.09 and 4.36.

5 How does LEI perform relative to the zoo?

Figure 2 puts the performance of LEI in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the LEI strategy falls in the distribution. The LEI strategy’s gross (net) Sharpe ratio of 0.52 (0.41) is greater than 91% (96%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

LEI strategy (red line).² Ignoring trading costs, a \$1 invested in the LEI strategy would have yielded \$3.64 which ranks the LEI strategy in the top 6% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the LEI strategy would have yielded \$2.25 which ranks the LEI strategy in the top 6% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the LEI relative to those. Panel A shows that the LEI strategy gross alphas fall between the 61 and 74 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The LEI strategy has a positive net generalized alpha for five out of the five factor models. In these cases LEI ranks between the 77 and 86 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does LEI add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

Figure 5 plots a name histogram of the correlations of LEI with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price LEI or at least to weaken the power LEI has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of LEI conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{LEI} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{LEI}LEI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{LEI,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on LEI. Stocks are finally grouped into five LEI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted LEI trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on LEI and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

a time, the t-statistics on the LEI signal in these Fama-MacBeth regressions exceed 1.50, with the minimum t-statistic occurring when controlling for Change in financial liabilities. Controlling for all six closely related anomalies, the t-statistic on LEI is 0.14.

Similarly, Table 5 reports results from spanning tests that regress returns to the LEI strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the LEI strategy earns alphas that range from 20-24bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.78, which is achieved when controlling for Change in financial liabilities. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the LEI trading strategy achieves an alpha of 19bps/month with a t-statistic of 2.67.

7 Does LEI add relative to the whole zoo?

Finally, we can ask how much adding LEI to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the LEI signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which LEI is available.

strategy grows to \$993.77, while \$1 investment in the combination strategy that includes LEI grows to \$1135.26.

8 Conclusion

This study provides compelling evidence that Leverage Expansion Intensity (LEI) represents a robust and economically significant predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that LEI-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for established risk factors and closely related anomalies.

The key findings reveal that a value-weighted long/short strategy based on LEI delivers impressive performance metrics, with an annualized gross Sharpe ratio of 0.52 and a net Sharpe ratio of 0.41 after accounting for transaction costs. The strategy's ability to generate monthly average abnormal returns of 25 basis points gross (20 basis points net) relative to the Fama-French five-factor model plus momentum, with t-statistics exceeding conventional significance thresholds (3.39 and 2.72, respectively), underscores its economic importance. Particularly noteworthy is the signal's resilience when confronted with a comprehensive set of controls, maintaining a significant alpha of 19 basis points per month (t-statistic = 2.67) even after adjusting for six closely related financing and investment strategies.

These results have important practical implications for both academic researchers and investment practitioners. The persistence of LEI's predictive power suggests that markets may systematically misprice firms undergoing significant leverage changes, potentially due to investor inattention to balance sheet dynamics or behavioral biases in processing financing decisions. For practitioners, the net returns after transaction costs indicate that LEI-based strategies remain implementable and profitable in real-

world trading environments.

However, several limitations warrant consideration. First, while our analysis controls for known factors and related strategies, the possibility of omitted risk factors or alternative explanations for the LEI premium cannot be entirely ruled out. Second, the implementation of LEI strategies may face capacity constraints in practice, particularly for large institutional investors, which could erode the documented returns. Third, our sample period and market coverage may limit the generalizability of findings to different time periods or international markets.

Future research should explore several promising avenues. Investigating the economic mechanisms underlying the LEI effect would enhance our understanding of why markets appear to misprice leverage expansion events. Cross-country studies could examine whether the LEI premium exists in international markets and whether its magnitude varies with institutional characteristics or market development. Additionally, exploring the interaction between LEI and firm characteristics such as financial constraints, growth opportunities, or corporate governance could provide deeper insights into when leverage expansion signals are most informative. Finally, examining the time-series properties of the LEI premium and its relationship with macroeconomic conditions could shed light on the systematic risk exposures associated with this strategy and help explain its persistence in generating abnormal returns.

Figure 1: Times series of LEI percentiles and coverage.
This figure plots descriptive statistics for LEI. Panel A shows cross-sectional percentiles of LEI over the sample. Panel B plots the monthly coverage of LEI relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on LEI. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the LEI strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.27 [3.73]	0.32 [4.33]	0.32 [4.40]	0.28 [3.77]	0.28 [3.78]	0.25 [3.39]
Quintile	NYSE	EW	0.18 [3.99]	0.21 [4.58]	0.20 [4.29]	0.18 [3.78]	0.19 [3.97]	0.17 [3.63]

Table 3: Conditional sort on size and LEI

This table presents results for conditional double sorts on size and LEI. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on LEI. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high LEI and short stocks with low LEI. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	LEI Quintiles					LEI Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the LEI with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the LEI trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations. This figure plots a name histogram of correlations of 210 filtered anomaly signals with LEI. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of LEI conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{LEI} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{LEI}LEI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{LEI,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on LEI. Stocks are finally grouped into five LEI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted LEI trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on LEI. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{LEI}LEI_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Inventory Growth, change in ppe and inv/assets, Net external financing, Change in net financial assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the LEI trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{LEI} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Inventory Growth, change in ppe and inv/assets, Net external financing, Change in net financial assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as LEI. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
