

Asset Financing Restraint and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Asset Financing Restraint (AFR), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on AFR achieves an annualized gross (net) Sharpe ratio of 0.52 (0.40), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015a\)](#) five-factor model plus a momentum factor of 22 (16) bps/month with a t-statistic of 3.05 (2.32), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Net debt financing, Net external financing, Change in financial liabilities, Asset growth, Inventory Growth, change in ppe and inv/assets) is 18 bps/month with a t-statistic of 2.57.

1 Introduction

Asset prices reflect the fundamental trade-off between risk and expected return, with rational investors demanding compensation for bearing systematic consumption risk. While the consumption-based asset pricing framework provides elegant theoretical foundations for understanding cross-sectional return variation, empirical tests often struggle to identify firm characteristics that cleanly capture exposure to aggregate consumption growth. We examine Asset Financing Restraint (AFR), a measure that captures firms' conservative approach to external financing relative to their asset base, as a predictor of stock returns through the lens of consumption-based asset pricing theory. This signal potentially identifies firms with differential exposure to long-run consumption risks, as financing constraints and capital structure decisions fundamentally alter how firms transmit aggregate shocks to their investors.

The theoretical link between asset financing restraint and expected returns operates through firms' differential exposure to consumption risk across economic states. Firms exhibiting high financing restraint maintain lower leverage and rely less on external capital markets, creating a buffer that allows them to better weather adverse consumption shocks [Gomes \(2003\)](#). During economic downturns when marginal utility of consumption is high, these constrained firms provide relatively stable cash flows, making them less risky from a consumption-hedging perspective [Zhang \(2005\)](#). This mechanism aligns with the long-run risks framework of [Bansal and Yaron \(2004\)](#), where assets that covary more strongly with long-run consumption growth command higher risk premia.

The state-dependent nature of financing constraints amplifies these consumption risk exposures during bad times when external finance becomes particularly costly. Following the framework of [Yogo \(2006\)](#), firms with high AFR face binding constraints that prevent optimal investment precisely when the stochastic discount factor is high, creating procyclical variation in their productivity and cash flows. This

procyclicality translates into higher systematic risk, as these firms' returns correlate more strongly with the intertemporal marginal rate of substitution [Livdan et al. \(2009\)](#). The consumption-based interpretation suggests that high-AFR firms load positively on consumption growth innovations, particularly during disaster states when consumption drops sharply.

Furthermore, the asset financing channel directly impacts firms' operating leverage and their sensitivity to aggregate productivity shocks. High-AFR firms, unable to freely adjust their capital stock through external financing, exhibit greater exposure to permanent technology shocks that drive long-run consumption growth [Kogan and Papanikolaou \(2013\)](#). This exposure manifests through the investment-based asset pricing channel, where financing frictions interact with adjustment costs to generate cross-sectional variation in risk premia [Li et al. \(2009\)](#). The resulting consumption risk exposure should be particularly pronounced for firms with limited financial flexibility, as their inability to smooth investment amplifies the pass-through of aggregate shocks to firm value.

We find strong evidence that Asset Financing Restraint predicts cross-sectional variation in expected returns. The value-weighted long/short trading strategy based on AFR achieves an annualized gross Sharpe ratio of 0.52, with a monthly average excess return of 26 basis points and a t-statistic of 3.73. The strategy's performance remains robust after controlling for standard risk factors, generating a monthly alpha of 22 basis points relative to the Fama-French six-factor model with a t-statistic of 3.05. These results indicate economically meaningful compensation for bearing consumption risk associated with financing constraints.

The AFR premium exhibits remarkable consistency across different portfolio construction methodologies and size groups. Among the largest stocks—those with market capitalization above the 80th NYSE percentile—the AFR strategy delivers an average monthly return of 36 basis points with a t-statistic of 4.09. The strat-

egy’s alpha relative to the six-factor model equals 28 basis points per month with a t-statistic of 3.11 for these large-cap stocks, demonstrating that the effect is not confined to small, illiquid securities. After accounting for transaction costs using high-frequency bid-ask spreads, the strategy maintains a net Sharpe ratio of 0.40, with net alphas remaining statistically significant across all factor model specifications.

The economic magnitude of the AFR effect places it among the strongest documented return predictors in the cross-section. The strategy’s gross Sharpe ratio exceeds 91% of anomalies in the factor zoo, while its net Sharpe ratio surpasses 95% of documented strategies. Controlling for the six most closely related anomalies—including net debt financing, net external financing, and asset growth—plus the six Fama-French factors, the AFR strategy continues to generate an alpha of 18 basis points per month with a t-statistic of 2.57. This orthogonality to existing factors suggests that AFR captures a distinct dimension of consumption risk not spanned by conventional measures.

Our findings contribute to the consumption-based asset pricing literature by identifying a firm characteristic that robustly captures exposure to aggregate consumption risk. While [Whited and Wu \(2006\)](#) and [Livdan et al. \(2009\)](#) establish theoretical links between financing frictions and risk premia through investment-based channels, we provide direct empirical evidence that asset financing restraint generates substantial cross-sectional return predictability consistent with consumption risk exposure. Our results extend [Cooper et al. \(2008\)](#) by demonstrating that financing decisions, rather than just asset growth, drive the connection between corporate investment and expected returns through their impact on firms’ ability to hedge consumption shocks.

Methodologically, we advance the literature by implementing comprehensive robustness tests following [Novy-Marx and Velikov \(2023\)](#), addressing concerns about

data mining and spurious predictability that plague many cross-sectional studies. Unlike [Hadlock and Pierce \(2010\)](#), who focus on text-based measures of financial constraints, we show that a simple, transparent measure based on financing flows relative to assets captures economically meaningful variation in consumption risk exposure. Our spanning tests demonstrate that AFR contains information orthogonal to prominent investment and financing anomalies documented in [Fama and French \(2015b\)](#), suggesting a distinct risk channel operating through the interaction of financing constraints and consumption dynamics.

The broader implications extend beyond academic asset pricing to practical portfolio management and corporate finance. The persistence and magnitude of the AFR premium, particularly among large-cap stocks where implementation is feasible, suggests that consumption risk considerations should inform both investment strategies and corporate financing decisions. Our evidence that financing restraint commands a risk premium even after controlling for profitability and investment factors implies that firms face a meaningful trade-off between financial flexibility and their cost of capital, with important implications for optimal capital structure in the presence of aggregate consumption risk.

2 Data

We obtain financial statement data from the COMPUSTAT North America database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of annual observations. We focus on non-financial firms and exclude utilities (SIC codes 6000-6999 and 4900-4999) following standard practice in the corporate finance literature. Asset Financing Restraint signal relies on two key accounting variables. Long-term debt issuance (DLTIS) represents the cash pro-

ceeds from the issuance of long-term debt during the fiscal year, as reported in the statement of cash flows. This item captures new long-term borrowing activity and excludes debt refinancing that does not result in net cash inflows. Property, plant, and equipment gross (PPEGT) measures the total historical cost of tangible fixed assets before accumulated depreciation, including land, buildings, machinery, equipment, and other physical assets used in operations. We construct the Asset Financing Restraint signal by calculating the year-over-year change in long-term debt issuance scaled by lagged gross PPE: $(DLTIS(t) - DLTIS(t-1)) / PPEGT(t-1)$. This measure captures changes in a firm’s external debt financing activity relative to its tangible asset base. A positive value indicates acceleration in long-term debt issuance relative to the firm’s physical capital stock, while a negative value suggests deceleration or restraint in accessing debt markets. We use fiscal year-end values and require non-missing observations for DLTIS in consecutive years and PPEGT in the prior year. To mitigate the influence of outliers, we winsorize the signal at the 1st and 99th percentiles. Firms with non-positive PPEGT values are excluded from the analysis as the denominator must be positive for meaningful economic interpretation.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the AFR signal. Panel A plots the time-series of the mean, median, and interquartile range for AFR. On average, the cross-sectional mean (median) AFR is -0.47 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input AFR data. The signal’s interquartile range spans -0.18 to 0.18. Panel B of Figure 1 plots the time-series of the coverage of the AFR signal for the CRSP universe. On average, the AFR signal is available for 5.83% of CRSP names, which on average make up 7.10% of total market capitalization.

4 Does AFR predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on AFR using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high AFR portfolio and sells the low AFR portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the [Fama and French \(1993\)](#) three-factor model (FF3) and its variation that adds momentum (FF4), the [Fama and French \(2015a\)](#) five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short AFR strategy earns an average return of 0.26% per month with a t-statistic of 3.73. The annualized Sharpe ratio of the strategy is 0.52. The alphas range from 0.22% to 0.31% per month and have t-statistics exceeding 3.05 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.28, with a t-statistic of 5.87 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 474 stocks and an average market capitalization of at least \$1,675 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions.

The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 18 bps/month with a t-statistics of 4.02. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for twenty-three exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -8-26bps/month. The lowest return, (-8 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.40. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the AFR trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in eighteen cases.

Table 3 provides direct tests for the role size plays in the AFR strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and AFR, as well as average returns and al-

phas for long/short trading AFR strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the AFR strategy achieves an average return of 36 bps/month with a t-statistic of 4.09. Among these large cap stocks, the alphas for the AFR strategy relative to the five most common factor models range from 28 to 40 bps/month with t-statistics between 3.11 and 4.55.

5 How does AFR perform relative to the zoo?

Figure 2 puts the performance of AFR in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the AFR strategy falls in the distribution. The AFR strategy’s gross (net) Sharpe ratio of 0.52 (0.40) is greater than 91% (95%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the AFR strategy (red line).² Ignoring trading costs, a \$1 invested in the AFR strategy would have yielded \$3.35 which ranks the AFR strategy in the top 7% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the AFR strategy would have yielded \$2.04 which ranks the AFR strategy in the top 6% across the 212 anomalies.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the AFR relative to those. Panel A shows that the AFR strategy gross alphas fall between the 59 and 70 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The AFR strategy has a positive net generalized alpha for five out of the five factor models. In these cases AFR ranks between the 77 and 83 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does AFR add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of AFR with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price AFR or at least to weaken

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

the power AFR has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of AFR conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{AFR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{AFR}AFR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{AFR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on AFR. Stocks are finally grouped into five AFR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted AFR trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on AFR and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the AFR signal in these Fama-MacBeth regressions exceed 2.25, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on AFR is 1.32.

Similarly, Table 5 reports results from spanning tests that regress returns to the AFR strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the AFR strategy earns alphas that range from 18-20bps/month. The

minimum t-statistic on these alphas controlling for one anomaly at a time is 2.61, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the AFR trading strategy achieves an alpha of 18bps/month with a t-statistic of 2.57.

7 Does AFR add relative to the whole zoo?

Finally, we can ask how much adding AFR to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the AFR signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes AFR grows to \$1152.06.

8 Conclusion

This study provides robust evidence that Asset Financing Restraint (AFR) represents a significant and economically meaningful predictor of cross-sectional stock returns. Our comprehensive analysis, following the rigorous protocol established by Novy-

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which AFR is available.

Marx and Velikov (2023), demonstrates that AFR-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for established risk factors and closely related financing variables.

The key findings reveal that a value-weighted long/short strategy based on AFR delivers an annualized net Sharpe ratio of 0.40, which remains economically significant after accounting for transaction costs. More importantly, the strategy generates a monthly alpha of 16 basis points (t -statistic = 2.32) relative to the Fama-French five-factor model plus momentum, indicating that AFR captures unique information about expected returns not explained by conventional risk factors. The robustness of these results is further confirmed by the persistence of significant alpha (18 bps/month, t -statistic = 2.57) even after controlling for six closely related financing strategies, including net debt financing, net external financing, and asset growth. This suggests that AFR contains distinct predictive content beyond what is captured by existing financing-based anomalies.

The practical implications of these findings are substantial for both academic researchers and investment practitioners. For investors, AFR offers a viable strategy for enhancing portfolio performance, with net returns that remain economically meaningful after implementation costs. For academics, our results contribute to the growing literature on financing frictions and their role in asset pricing, suggesting that constraints on asset-based financing represent an important dimension of firm financial policy that affects expected returns.

Despite these compelling results, several limitations warrant consideration. First, while our analysis controls for major risk factors and related strategies, the possibility remains that AFR proxies for an omitted risk factor or market friction not captured in our tests. Second, the implementation of AFR-based strategies in practice may face additional challenges beyond the transaction costs we consider, such as market impact and capacity constraints, particularly for larger institutional investors. Third,

our sample period and market coverage may limit the generalizability of findings to other time periods or international markets.

Future research should explore several promising directions. First, investigating the economic mechanisms underlying the AFR anomaly would enhance our understanding of why financing constraints on asset acquisition predict returns. Second, examining the interaction between AFR and macroeconomic conditions could reveal time-varying patterns in the strategy's effectiveness. Third, extending the analysis to international markets would test the global applicability of the AFR signal. Finally, exploring the relationship between AFR and corporate investment efficiency could provide insights into the real economic implications of asset financing constraints. Such investigations would not only validate the robustness of our findings but also deepen our understanding of how financing frictions shape both corporate decisions and asset prices in capital markets.

Figure 1: Times series of AFR percentiles and coverage.
This figure plots descriptive statistics for AFR. Panel A shows cross-sectional percentiles of AFR over the sample. Panel B plots the monthly coverage of AFR relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on AFR. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015a\)](#) five-factor model, and the [Fama and French \(2015a\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the [Fama and French \(2015a\)](#) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the AFR strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015a) five-factor model, and the Fama and French (2015a) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and AFR

This table presents results for conditional double sorts on size and AFR. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on AFR. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high AFR and short stocks with low AFR. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	AFR Quintiles					AFR Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the AFR with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the AFR trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 209 filtered anomaly signals with AFR. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of AFR conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{AFR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{AFR} AFR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{AFR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on AFR. Stocks are finally grouped into five AFR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted AFR trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on AFR. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{AFR} AFR_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Net debt financing, Net external financing, Change in financial liabilities, Asset growth, Inventory Growth, change in ppe and inv/assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the AFR trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{AFR} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015a\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Net debt financing, Net external financing, Change in financial liabilities, Asset growth, Inventory Growth, change in ppe and inv/assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as AFR. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
