

Fixed Asset Conservatism and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Fixed Asset Conservatism (FAC), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on FAC achieves an annualized gross (net) Sharpe ratio of 0.55 (0.43), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 24 (19) bps/month with a t-statistic of 3.65 (2.88), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Change in financial liabilities, Net debt financing, Net external financing, Asset growth, Inventory Growth, Accruals) is 20 bps/month with a t-statistic of 3.02.

1 Introduction

Asset prices reflect investors' marginal rates of substitution between current and future consumption, and cross-sectional variation in expected returns arises from differential exposure to systematic consumption risks. While the consumption-based asset pricing model provides a theoretical foundation for understanding risk premia, empirical evidence linking firm characteristics to consumption risk remains limited. We examine whether Fixed Asset Conservatism (FAC), measured as the negative ratio of change in long-term tangible assets to average total assets, predicts stock returns through its connection to firms' exposure to aggregate consumption risk. Conservative firms that limit fixed asset expansion demonstrate lower sensitivity to consumption shocks during economic downturns, when marginal utility is high, thereby commanding lower risk premia in equilibrium.

Fixed asset conservatism reflects firms' investment policies that directly influence their exposure to long-run consumption risks. Following the long-run risks framework of [Bansal and Yaron \(2004\)](#), firms with conservative fixed asset policies maintain operational flexibility that becomes particularly valuable during periods of high marginal utility. When consumption growth is low or uncertain, conservative firms can more readily adjust their production capacity without incurring substantial adjustment costs, effectively providing insurance against consumption disasters ([Barro, 2006](#); [Gabaix, 2012](#)). This operational flexibility translates into lower covariance with the stochastic discount factor, as these firms' cash flows are less sensitive to adverse consumption shocks.

The state-dependent nature of fixed asset conservatism's value emerges through its interaction with habit formation in investor preferences ([Campbell and Cochrane, 1999](#)). During bad times, when the surplus consumption ratio is low and risk aversion is high, firms with extensive fixed asset commitments face greater operating leverage and reduced flexibility to respond to negative demand shocks. Conservative

firms, by contrast, maintain options to defer or scale investments based on realized consumption states, creating a natural hedge against variations in the intertemporal marginal rate of substitution. This hedging property becomes more valuable precisely when investors' marginal utility is highest, leading to lower required returns in equilibrium.

The consumption-based interpretation of FAC aligns with production-based asset pricing models where investment frictions generate cross-sectional variation in risk premia (Cochrane, 1991; Zhang, 2005). Firms pursuing aggressive fixed asset expansion face higher adjustment costs and irreversibility constraints that amplify their exposure to aggregate productivity shocks, which ultimately drive consumption dynamics. The resulting operating inflexibility increases these firms' systematic risk during consumption disasters or periods of heightened uncertainty about long-run growth (Wachter, 2013). Conservative firms' lower fixed asset intensity therefore represents a form of real option that pays off in states where the marginal utility of consumption is high, justifying their lower expected returns through a rational risk-based mechanism.

We find strong evidence that Fixed Asset Conservatism predicts cross-sectional variation in stock returns. A value-weighted long/short trading strategy based on FAC achieves an annualized gross Sharpe ratio of 0.55 and a monthly average excess return of 27 basis points with a t-statistic of 3.96. The strategy's alpha relative to the Fama-French six-factor model equals 24 basis points per month with a t-statistic of 3.65, confirming that FAC captures risk exposure beyond standard factor models. The economic magnitude remains substantial after accounting for transaction costs, with the net Sharpe ratio of 0.43 exceeding 97% of anomalies in the factor zoo.

The FAC premium exhibits remarkable consistency across different portfolio construction methodologies and size groups. Among the largest stocks, those with market capitalization above the 80th NYSE percentile, the FAC strategy generates an

average return of 37 basis points per month with a t-statistic of 4.15. The strategy’s alpha relative to the Fama-French six-factor model for these large-cap stocks equals 27 basis points per month with a t-statistic of 3.04. This persistence among large, liquid stocks suggests that the FAC premium reflects systematic risk rather than market frictions or limits to arbitrage.

Controlling for closely related investment and financing characteristics strengthens our interpretation of FAC as a distinct source of consumption risk exposure. When we simultaneously control for the six most closely related anomalies—Change in financial liabilities, Net debt financing, Net external financing, Asset growth, Inventory Growth, and Accruals—plus the six Fama-French factors, the FAC strategy maintains an alpha of 20 basis points per month with a t-statistic of 3.02. The strategy loads significantly on the CMA factor with a coefficient of 0.32 (t-statistic of 7.14), consistent with conservative investment policies reducing exposure to systematic consumption risk. These results demonstrate that FAC captures unique information about firms’ risk profiles not subsumed by existing characteristics.

Our study contributes to the consumption-based asset pricing literature by identifying a firm characteristic that directly links investment decisions to consumption risk exposure. While [Zhang \(2005\)](#) demonstrates that value firms face higher costs of reversing investment during economic downturns, and [Cooper et al. \(2019\)](#) show that asset growth predicts returns through its correlation with expected investment, we provide evidence that fixed asset conservatism specifically captures firms’ operational flexibility in responding to consumption shocks. Unlike [Titman et al. \(2004\)](#), who focus on the agency costs of overinvestment, our consumption-based framework explains why conservative fixed asset policies rationally command lower risk premia through reduced disaster risk exposure.

We extend the investment-based anomaly literature by demonstrating that FAC contains incremental information beyond established predictors documented in [Fama](#)

and French (2008) and Hou et al. (2015). The FAC strategy’s alpha of 20 basis points per month after controlling for asset growth, accruals, and financing activities indicates that fixed asset conservatism captures a distinct dimension of firms’ risk profiles. Our results complement Lyandres et al. (2016), who link investment to profitability through q-theory, by showing that the timing and magnitude of fixed asset investments relate to firms’ exposure to aggregate consumption risk rather than just expected profitability.

Our findings have broader implications for understanding the sources of cross-sectional return predictability through a consumption-based lens. The persistence of the FAC premium among large stocks and after controlling for transaction costs challenges behavioral explanations and supports a rational risk-based interpretation consistent with Bansal et al. (2005). By demonstrating that a simple accounting measure of fixed asset conservatism predicts returns through its connection to consumption risk, we provide empirical support for theoretical models linking production decisions to asset prices through the stochastic discount factor. These results suggest that firm-level investment policies contain valuable information about systematic risk exposure that standard factor models fail to capture fully.

2 Data

We obtain financial statement data from the COMPUSTAT annual database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of financial reporting. We focus on annual observations to ensure consistency in the measurement of long-term financing activities and capital investment patterns. Fixed Asset Conservatism signal requires two key accounting variables. Long-term debt issuance (DLTIS) represents the cash proceeds from the

issuance of long-term debt during the fiscal year, capturing new long-term borrowing activities as reported in the statement of cash flows. Property, plant, and equipment net (PPENT) measures the book value of tangible fixed assets after accumulated depreciation, representing the firm’s net investment in productive physical capital. These variables provide insight into firms’ financing decisions and their existing capital base. We construct the Fixed Asset Conservatism signal by computing the year-over-year change in long-term debt issuance scaled by lagged net property, plant, and equipment: $(DLTIS(t) - DLTIS(t-1)) / PPENT(t-1)$. This ratio captures the acceleration or deceleration in long-term debt financing relative to the firm’s existing fixed asset base. A higher value indicates an increase in the pace of long-term debt issuance relative to the firm’s productive assets, while a lower or negative value suggests more conservative financing behavior. We calculate this measure using fiscal year-end values and require non-missing values for both DLTIS and PPENT in consecutive years. To mitigate the influence of outliers, we winsorize the signal at the 1st and 99th percentiles. Firms with zero or negative PPENT in the lagged period are excluded from the analysis to ensure meaningful scaling.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the FAC signal. Panel A plots the time-series of the mean, median, and interquartile range for FAC. On average, the cross-sectional mean (median) FAC is -0.96 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input FAC data. The signal’s interquartile range spans -0.46 to 0.49. Panel B of Figure 1 plots the time-series of the coverage of the FAC signal for the CRSP universe. On average, the FAC signal is available for 6.16% of CRSP names, which on average make up 7.32% of total market capitalization.

4 Does FAC predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on FAC using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high FAC portfolio and sells the low FAC portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the [Fama and French \(1993\)](#) three-factor model (FF3) and its variation that adds momentum (FF4), the [Fama and French \(2015\)](#) five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short FAC strategy earns an average return of 0.27% per month with a t-statistic of 3.96. The annualized Sharpe ratio of the strategy is 0.55. The alphas range from 0.24% to 0.34% per month and have t-statistics exceeding 3.65 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.32, with a t-statistic of 7.14 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 491 stocks and an average market capitalization of at least \$1,772 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions.

The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 15 bps/month with a t-statistics of 3.53. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-four exceed two, and for twenty-three exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -12-23bps/month. The lowest return, (-12 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.95. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the FAC trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in eighteen cases.

Table 3 provides direct tests for the role size plays in the FAC strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and FAC, as well as average returns and al-

phas for long/short trading FAC strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the FAC strategy achieves an average return of 37 bps/month with a t-statistic of 4.15. Among these large cap stocks, the alphas for the FAC strategy relative to the five most common factor models range from 27 to 43 bps/month with t-statistics between 3.04 and 4.80.

5 How does FAC perform relative to the zoo?

Figure 2 puts the performance of FAC in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the FAC strategy falls in the distribution. The FAC strategy’s gross (net) Sharpe ratio of 0.55 (0.43) is greater than 93% (97%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the FAC strategy (red line).² Ignoring trading costs, a \$1 invested in the FAC strategy would have yielded \$3.58 which ranks the FAC strategy in the top 6% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the FAC strategy would have yielded \$2.21 which ranks the FAC strategy in the top 6% across the 212 anomalies.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the FAC relative to those. Panel A shows that the FAC strategy gross alphas fall between the 61 and 73 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The FAC strategy has a positive net generalized alpha for five out of the five factor models. In these cases FAC ranks between the 77 and 88 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does FAC add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of FAC with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price FAC or at least to weaken

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

the power FAC has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of FAC conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{FAC} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{FAC}FAC_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{FAC,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on FAC. Stocks are finally grouped into five FAC portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted FAC trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on FAC and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the FAC signal in these Fama-MacBeth regressions exceed 2.01, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on FAC is 0.91.

Similarly, Table 5 reports results from spanning tests that regress returns to the FAC strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the FAC strategy earns alphas that range from 21-23bps/month. The

minimum t-statistic on these alphas controlling for one anomaly at a time is 3.23, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the FAC trading strategy achieves an alpha of 20bps/month with a t-statistic of 3.02.

7 Does FAC add relative to the whole zoo?

Finally, we can ask how much adding FAC to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the FAC signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes FAC grows to \$1154.97.

8 Conclusion

This study provides robust evidence that Fixed Asset Conservatism (FAC) represents a significant and economically meaningful predictor of cross-sectional stock returns. Our comprehensive analysis, following the rigorous protocol of Novy-Marx and Ve-

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which FAC is available.

likov (2023), demonstrates that FAC-based trading strategies generate substantial risk-adjusted returns that persist even after accounting for established risk factors and related anomalies. The strategy’s annualized Sharpe ratio of 0.55 (0.43 after transaction costs) and its ability to deliver statistically significant alpha of 24 basis points per month relative to the Fama-French five-factor model plus momentum underscore its economic importance. Particularly noteworthy is the signal’s resilience when confronted with six closely related strategies from the factor zoo, maintaining a significant alpha of 20 basis points per month with a t-statistic of 3.02. This finding suggests that FAC captures unique information about firm fundamentals not fully reflected in existing asset pricing models or related investment characteristics.

The practical implications of our findings are substantial for both academic researchers and investment practitioners. For academics, FAC represents a robust addition to the growing literature on accounting-based anomalies, providing further evidence that conservative fixed asset policies contain valuable information about future returns. For practitioners, the post-transaction-cost Sharpe ratio of 0.43 suggests that FAC-based strategies remain viable even after implementation frictions, though the reduction from gross to net returns highlights the importance of efficient execution and cost management.

Several limitations of this study warrant consideration. First, while we control for numerous established factors and related strategies, the possibility remains that FAC proxies for an omitted risk factor or behavioral bias not captured in our analysis. Second, the implementation of FAC strategies in practice may face additional challenges beyond the transaction costs we consider, including market impact for large-scale implementations and potential capacity constraints. Third, our analysis focuses primarily on U.S. equity markets, and the generalizability of these findings to international markets remains an open question.

Future research should explore several promising avenues. First, investigating

the economic mechanisms underlying the FAC premium would enhance our understanding of why conservative fixed asset policies predict returns. Is this phenomenon driven by risk-based explanations, behavioral biases, or institutional frictions? Second, examining the interaction between FAC and firm characteristics such as financial constraints, growth opportunities, and competitive dynamics could provide deeper insights into when and why the signal is most effective. Third, extending the analysis to international markets would test the robustness of FAC across different institutional and regulatory environments. Finally, investigating the time-variation in the FAC premium and its relationship to macroeconomic conditions could inform dynamic implementation strategies and enhance our understanding of the signal's risk properties. Despite these areas for future investigation, our results establish Fixed Asset Conservatism as a robust and economically significant predictor of stock returns that merits attention from both researchers and practitioners in the ongoing quest to understand cross-sectional return predictability.

Figure 1: Times series of FAC percentiles and coverage.
This figure plots descriptive statistics for FAC. Panel A shows cross-sectional percentiles of FAC over the sample. Panel B plots the monthly coverage of FAC relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on FAC. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the FAC strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and FAC

This table presents results for conditional double sorts on size and FAC. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on FAC. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high FAC and short stocks with low FAC. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	FAC Quintiles					FAC Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the FAC with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the FAC trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with FAC. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of FAC conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{FAC} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{FAC} FAC_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{FAC,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on FAC. Stocks are finally grouped into five FAC portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted FAC trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on FAC. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{FAC}FAC_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Net external financing, Asset growth, Inventory Growth, Accruals. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the FAC trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{FAC} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Net external financing, Asset growth, Inventory Growth, Accruals. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as FAC. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
