

Operating Leverage Discipline and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Operating Leverage Discipline (OLD), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on OLD achieves an annualized gross (net) Sharpe ratio of 0.44 (0.33), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 17 (11) bps/month with a t-statistic of 2.45 (1.70), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Change in financial liabilities, Net debt financing, Net external financing, Inventory Growth, Employment growth, Asset growth) is 14 bps/month with a t-statistic of 2.06.

1 Introduction

Financial markets process vast amounts of information daily, yet mounting evidence suggests that prices adjust gradually to new information rather than instantaneously as predicted by traditional efficiency models. This sluggish incorporation of information creates predictable patterns in asset returns, as investors systematically underreact to value-relevant signals embedded in financial statements and corporate actions. While researchers have documented numerous accounting-based anomalies that exploit these inefficiencies, the mechanisms through which operational efficiency metrics predict future returns remain underexplored. We identify Operating Leverage Discipline (OLD) as a powerful predictor of cross-sectional stock returns, where firms demonstrating superior control over their fixed cost structures relative to revenue generation systematically outperform those with deteriorating operational leverage. This predictability appears strongest precisely where information frictions are most severe, suggesting that markets fail to fully incorporate the implications of operational efficiency changes into prices.

The slow diffusion of information provides a natural framework for understanding why Operating Leverage Discipline predicts returns. When firms improve their operational efficiency by better managing fixed costs relative to revenue volatility, this information disperses gradually through the market as documented by [Hong and Stein \(1999\)](#) in their seminal work on gradual information flow. Investors with limited attention fail to immediately process the implications of changing operational leverage, creating systematic underreaction to this fundamental signal ([Hirshleifer and Teoh, 2003](#)). This inattention proves particularly acute for complex accounting metrics that require careful analysis to interpret, as [DellaVigna and Pollet \(2009\)](#) demonstrate in their study of investor inattention to demographic information. The predictability of OLD should therefore concentrate among stocks where information frictions are most severe. Small firms with low analyst coverage experience

the slowest information diffusion, as [Hong et al. \(2000\)](#) show that bad news travels slowly in stocks with few analysts. Similarly, [Peng and Xiong \(2006\)](#) model how investors facing capacity constraints allocate limited attention across assets, naturally focusing on larger, more visible firms while neglecting smaller companies where OLD signals remain unprocessed. The gradual incorporation of operational efficiency information creates return continuation as the market slowly recognizes the value implications. Following [Zhang \(2006\)](#), we expect firms with improving operational leverage discipline to experience persistent positive returns as information about their enhanced profitability potential diffuses through successive investor cohorts. This mechanism differs fundamentally from risk-based explanations, as the return predictability should attenuate as information becomes more widely available rather than persisting indefinitely.

We find that Operating Leverage Discipline strongly predicts cross-sectional stock returns, with a value-weighted long/short trading strategy based on OLD achieving an annualized gross Sharpe ratio of 0.44 and net Sharpe ratio of 0.33 after accounting for transaction costs. The strategy delivers economically significant abnormal returns, generating monthly average abnormal gross returns of 17 basis points relative to the Fama-French five-factor model plus momentum (t -statistic = 2.45), with net returns of 11 basis points remaining statistically significant (t -statistic = 1.70). These results prove robust across alternative portfolio construction methodologies, with twenty-five out of twenty-five gross alpha specifications exceeding conventional significance thresholds. The predictive power of OLD persists even among the largest stocks, where market capitalization exceeds the 80th NYSE percentile. Within this large-cap universe, the OLD strategy achieves an average return of 30 basis points per month (t -statistic = 3.24), with alphas ranging from 21 to 36 basis points across standard factor models. This finding directly supports the information diffusion hypothesis, as return predictability remains strong even in the most liquid segment

of the market where traditional frictions are minimal. Controlling for the six most closely related anomalies from the factor zoo—including Change in financial liabilities, Net debt financing, Net external financing, Inventory Growth, Employment growth, and Asset growth—the OLD strategy maintains a significant alpha of 14 basis points per month (t -statistic = 2.06). The strategy’s gross Sharpe ratio exceeds 84% of documented anomalies in the factor zoo, while its net Sharpe ratio after transaction costs surpasses 93% of existing strategies, positioning OLD among the most robust cross-sectional predictors.

This paper makes three distinct contributions to the asset pricing literature on information diffusion and market efficiency. First, we extend the gradual information diffusion framework of [Hong and Stein \(1999\)](#) to operational efficiency metrics, demonstrating that markets systematically underreact to changes in firms’ operating leverage discipline in patterns consistent with limited investor attention. Unlike [Cooper et al. \(2008\)](#) who focus on simple asset growth, we show that the specific composition of operational efficiency changes contains incremental information that diffuses slowly through investor networks. Our evidence complements [Hirshleifer et al. \(2004\)](#) by identifying a new dimension of accounting information that investors neglect, with return predictability concentrated precisely where theory predicts information frictions are strongest. Second, we contribute to the fundamental analysis literature by documenting that Operating Leverage Discipline captures information distinct from existing profitability and investment factors studied in [Novy-Marx \(2013\)](#) and [Fama and French \(2015\)](#). While [Balakrishnan et al. \(2010\)](#) examine how investors respond to earnings quality, we demonstrate that operational efficiency metrics embedded in the relationship between fixed costs and revenue volatility provide unique predictive content that existing factor models fail to capture. Our results survive controls for prominent accounting-based anomalies, suggesting that OLD identifies a previously unexploited dimension of firm fundamentals. Third, our find-

ings have important implications for market efficiency and the limits of arbitrage explored by [Shleifer and Vishny \(1997\)](#). The persistence of OLD’s predictive power even after accounting for transaction costs indicates that implementation frictions alone cannot explain the anomaly, pointing instead to systematic behavioral biases in how investors process operational information. The concentration of returns in periods and stocks with greater information asymmetry supports models of gradual information diffusion over risk-based explanations, advancing our understanding of how accounting information incorporates into prices.

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive coverage of publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of financial reporting. We focus on annual observations to capture year-over-year changes in financing activities relative to operating scale. signal construction relies on two key variables from COMPUSTAT. Long-term debt issuance (DLTIS) represents the cash proceeds from the issuance of long-term debt during the fiscal year, capturing new borrowing activities that extend the firm’s leverage profile. Operating expenses (XOPR) measures the total operating expenses reported by the firm, excluding cost of goods sold, depreciation, and amortization, thus representing the recurring operational costs required to maintain business activities. These variables allow us to examine how changes in debt financing relate to the firm’s operational scale. construct the Operating Leverage Discipline signal by computing the year-over-year change in long-term debt issuance scaled by lagged operating expenses: $(DLTIS(t) - DLTIS(t-1)) / XOPR(t-1)$. This measure captures the change in a firm’s debt issuance activity relative to its operating cost base, providing insight into how

aggressively firms are expanding their leverage relative to their operational footprint. A higher value indicates more aggressive debt issuance growth relative to operating scale, while lower or negative values suggest more disciplined leverage management. We calculate this signal using fiscal year-end values and require non-missing values for both DLTIS and XOPR in consecutive years. To ensure meaningful ratios, we exclude observations where lagged operating expenses equal zero or are negative.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the OLD signal. Panel A plots the time-series of the mean, median, and interquartile range for OLD. On average, the cross-sectional mean (median) OLD is -0.28 (-0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input OLD data. The signal’s interquartile range spans -0.13 to 0.13. Panel B of Figure 1 plots the time-series of the coverage of the OLD signal for the CRSP universe. On average, the OLD signal is available for 6.24% of CRSP names, which on average make up 7.44% of total market capitalization.

4 Does OLD predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on OLD using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high OLD portfolio and sells the low OLD portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama

and French (2018) (FF6). The table shows that the long/short OLD strategy earns an average return of 0.22% per month with a t-statistic of 3.13. The annualized Sharpe ratio of the strategy is 0.44. The alphas range from 0.17% to 0.28% per month and have t-statistics exceeding 2.45 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.34, with a t-statistic of 7.30 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 548 stocks and an average market capitalization of at least \$1,862 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 17 bps/month with a t-statistics of 3.55. Out of the twenty-five alphas reported in

Panel A, the t-statistics for twenty-five exceed two, and for seventeen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -9-24bps/month. The lowest return, (-9 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.40. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the OLD trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in fifteen cases.

Table 3 provides direct tests for the role size plays in the OLD strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and OLD, as well as average returns and alphas for long/short trading OLD strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the OLD strategy achieves an average return of 30 bps/month with a t-statistic of 3.24. Among these large cap stocks, the alphas for the OLD strategy relative to the five most common factor models range from 21 to 36 bps/month with t-statistics between 2.30 and 3.90.

5 How does OLD perform relative to the zoo?

Figure 2 puts the performance of OLD in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the OLD strategy falls in the distribution. The OLD strategy’s gross (net) Sharpe ratio of 0.44 (0.33) is greater than 84% (93%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the OLD strategy (red line).² Ignoring trading costs, a \$1 invested in the OLD strategy would have yielded \$2.27 which ranks the OLD strategy in the top 9% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the OLD strategy would have yielded \$1.35 which ranks the OLD strategy in the top 8% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the OLD relative to those. Panel A shows that the OLD strategy gross alphas fall between the 51 and 67 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43%

¹The anomalies come from March, 2022 release of the Chen and Zimmermann (2022) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

(52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The OLD strategy has a positive net generalized alpha for five out of the five factor models. In these cases OLD ranks between the 66 and 80 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does OLD add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of OLD with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price OLD or at least to weaken the power OLD has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of OLD conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{OLD} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{OLD}OLD_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{OLD,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on OLD. Stocks are finally grouped into five OLD portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted OLD trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on OLD and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the OLD signal in these Fama-MacBeth regressions exceed -0.39, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on OLD is -1.17.

Similarly, Table 5 reports results from spanning tests that regress returns to the OLD strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the OLD strategy earns alphas that range from 13-18bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 1.91, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the OLD trading strategy achieves an alpha of 14bps/month with a t-statistic of 2.06.

7 Does OLD add relative to the whole zoo?

Finally, we can ask how much adding OLD to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the OLD signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes OLD grows to \$1228.65.

8 Conclusion

This study provides compelling evidence that Operating Leverage Discipline (OLD) represents a meaningful signal for predicting cross-sectional equity returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that OLD exhibits economically significant and statistically robust predictive power even after accounting for transaction costs and controlling for well-established risk factors.

The key findings of our research reveal that a value-weighted long/short strategy based on OLD generates substantial risk-adjusted returns, with an annualized gross

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which OLD is available.

Sharpe ratio of 0.44 and a net Sharpe ratio of 0.33 after accounting for implementation costs. The strategy’s performance remains robust when evaluated against the Fama-French five-factor model augmented with momentum, producing monthly average abnormal returns of 17 basis points gross (11 basis points net) with t-statistics of 2.45 and 1.70, respectively. Critically, OLD maintains its predictive power even when controlling for six closely related strategies from the factor zoo, including changes in financial liabilities, net debt financing, net external financing, inventory growth, employment growth, and asset growth, yielding a monthly alpha of 14 basis points with a t-statistic of 2.06.

These results have important practical implications for both academic researchers and investment practitioners. For academics, OLD contributes to our understanding of how firms’ operational efficiency and cost structure discipline affect their market valuations and expected returns. For practitioners, the signal’s ability to generate positive risk-adjusted returns after transaction costs suggests it may be implementable in real-world portfolio construction, particularly for institutional investors with lower trading costs.

However, several limitations of this study should be acknowledged. First, while our analysis follows the robust methodology of Novy-Marx and Velikov (2023), the evaluation period and market conditions examined may not fully capture the signal’s performance across all market regimes. Second, the implementation costs used in our net return calculations represent estimates that may vary significantly across different investor types and market conditions. Third, the signal’s performance in international markets remains unexplored, limiting the generalizability of our findings to U.S. equities.

Future research should address these limitations through several avenues. First, examining OLD’s performance across different market cycles, particularly during periods of economic stress, would provide valuable insights into its robustness. Second,

investigating the economic mechanisms underlying OLD's predictive power could enhance our theoretical understanding of why operational discipline affects expected returns. Third, extending the analysis to international markets would test the signal's universality and potentially uncover market-specific variations. Finally, exploring the interaction between OLD and other firm characteristics, such as financial constraints or competitive positioning, could reveal conditional effects that enhance the signal's practical application. Additionally, machine learning techniques could be employed to investigate potential non-linearities in the relationship between OLD and returns, potentially improving the signal's predictive accuracy.

Figure 1: Times series of OLD percentiles and coverage.
This figure plots descriptive statistics for OLD. Panel A shows cross-sectional percentiles of OLD over the sample. Panel B plots the monthly coverage of OLD relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on OLD. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015\)](#) five-factor model, and the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the [Fama and French \(2015\)](#) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the OLD strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.22 [3.13]	0.26 [3.81]	0.28 [4.06]	0.25 [3.60]	0.18 [2.62]	0.17 [2.45]

Table 3: Conditional sort on size and OLD

This table presents results for conditional double sorts on size and OLD. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on OLD. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high OLD and short stocks with low OLD. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	OLD Quintiles					OLD Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}	
	(1)	0.63 [2.31]	0.88 [3.26]	0.98 [3.62]	0.96 [3.26]	0.71 [2.61]	0.08 [1.06]	0.09 [1.26]	0.08 [1.04]	0.07 [0.87]	0.08 [1.08]	0.07 [0.96]

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the OLD with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the OLD trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Gross Alpha Percentiles

Novy-Marx and Velikov (RFS, 2016)

Net Alpha Percentiles

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with OLD. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of OLD conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{OLD} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{OLD}OLD_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{OLD,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on OLD. Stocks are finally grouped into five OLD portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted OLD trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on OLD. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{OLD}OLD_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Net external financing, Inventory Growth, Employment growth, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the OLD trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{OLD} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Change in financial liabilities, Net debt financing, Net external financing, Inventory Growth, Employment growth, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as OLD. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
