

Intangible Investment Restraint and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Intangible Investment Restraint (IIR), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on IIR achieves an annualized gross (net) Sharpe ratio of 0.43 (0.35), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 22 (19) bps/month with a t-statistic of 2.85 (2.49), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Net external financing, Net debt financing, Change in equity to assets, Total accruals, Asset growth, Accruals) is 19 bps/month with a t-statistic of 2.42.

1 Introduction

Asset prices reflect investors' marginal utility across states of nature, with risk premia emerging from the covariance between asset payoffs and stochastic discount factors. While consumption-based asset pricing models provide the theoretical foundation for understanding cross-sectional return variation, empirical evidence linking firm characteristics to consumption risk exposure remains incomplete. We identify a critical gap in understanding how firms' intangible investment decisions relate to their exposure to aggregate consumption shocks. Intangible Investment Restraint (IIR), measured as the negative change in intangible assets scaled by total assets, captures firms' strategic decisions to limit or reduce their commitments to knowledge capital, research capabilities, and organizational development. This restraint behavior potentially signals important information about firms' consumption risk profiles and their sensitivity to macroeconomic fluctuations.

Firms exhibiting high intangible investment restraint demonstrate lower exposure to consumption risk through multiple economic channels. The long-run risks model of [Bansal and Yaron \(2004\)](#) suggests that assets with differential exposure to persistent consumption growth shocks command different risk premia. Firms restraining intangible investments preserve financial flexibility and reduce their sensitivity to long-run productivity shocks that drive consumption dynamics. During economic downturns when marginal utility is high, these constrained firms maintain stronger cash positions and face lower adjustment costs, providing relative consumption insurance to investors ([Zhang, 2005](#)). The state-dependent nature of intangible investment decisions amplifies these effects during disaster scenarios. Following [Barro \(2006\)](#), firms with high IIR exhibit lower sensitivity to rare disaster risk because intangible capital destruction during economic catastrophes disproportionately affects firms with extensive intangible asset bases. The reduced operating leverage from limited intangible commitments decreases firms' exposure to systematic consump-

tion shocks that drive the intertemporal marginal rate of substitution. Additionally, habit formation models suggest that firms restraining intangible investments provide consumption smoothing benefits when habit-adjusted surplus consumption is low (Campbell and Cochrane, 1999). These firms’ conservative investment policies reduce their covariance with the consumption-based stochastic discount factor, particularly during periods of heightened consumption risk when investors’ marginal utility is most sensitive to wealth shocks.

The intangible investment restraint strategy delivers economically and statistically significant returns across multiple specifications. A value-weighted long/short trading strategy based on IIR achieves an annualized gross Sharpe ratio of 0.43 and a net Sharpe ratio of 0.35, placing it in the top decile of documented anomalies. The strategy generates monthly average abnormal gross returns of 22 basis points relative to the Fama-French six-factor model, with a t-statistic of 2.85, confirming robust performance after controlling for established risk factors. Among large-cap stocks exceeding the 80th NYSE size percentile, the IIR strategy maintains strong performance with average returns of 30 basis points per month and a t-statistic of 2.74, demonstrating that the effect persists beyond small, illiquid securities. The strategy’s alpha remains significant at 19 basis points per month with a t-statistic of 2.42 when controlling for both the six Fama-French factors and the six most closely related anomalies including asset growth and accruals. Net of transaction costs, the strategy generates positive generalized alphas across all five standard factor models, with the IIR strategy improving the achievable mean-variance efficient frontier in each case. The economic magnitude of these returns, combined with their persistence across size groups and robustness to alternative portfolio construction methodologies, establishes IIR as a distinct source of systematic return variation linked to consumption risk exposure.

This paper advances the consumption-based asset pricing literature by establish-

ing intangible investment restraint as a novel proxy for firms’ exposure to aggregate consumption risk. We extend [Eisfeldt and Papanikolaou \(2013\)](#) who document the importance of organization capital for asset prices by showing that the dynamic restraint of such investments, rather than levels, captures time-varying consumption risk exposure. Unlike [Peters and Wang \(2017\)](#) who focus on RD investment growth, we demonstrate that broad intangible investment restraint encompasses multiple dimensions of firms’ consumption hedging properties. Our findings complement [Li and Qiu \(2018\)](#) by revealing that the asset pricing implications of intangible capital extend beyond productivity shocks to fundamental consumption risk channels. The methodological innovation lies in our comprehensive treatment of intangible investment dynamics as signals of state-dependent marginal utility exposure, particularly during disaster scenarios and periods of high consumption volatility. We document that IIR-sorted portfolios exhibit distinct patterns of covariance with consumption-based factors that existing characteristics fail to capture fully. The strategy’s ability to expand the mean-variance efficient frontier net of costs when added to standard factor models demonstrates its unique contribution to understanding the cross-section through a consumption risk lens. These results have broader implications for theoretical models of production-based asset pricing, suggesting that firms’ intangible investment policies serve as observable instruments for their unobservable consumption risk profiles, thereby providing a bridge between real investment decisions and equilibrium risk premia in consumption-based frameworks.

2 Data

We obtain financial statement data from the COMPUSTAT Annual database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, span-

ning several decades of financial reporting. We focus on annual observations to ensure consistency in the measurement of investment activities and intangible asset positions. construction of our Intangible Investment Restraint signal relies on two key accounting variables. Increase in investments (IVCH) represents the cash outflow for acquisitions and investments during the fiscal year, capturing the firm’s expenditure on acquiring other businesses, purchasing investment securities, and making other long-term investments. This item reflects the investing activities section of the cash flow statement and measures the firm’s commitment of resources toward external growth opportunities. Intangible assets (INTAN) represents the book value of all intangible assets reported on the balance sheet, including goodwill, patents, trademarks, customer relationships, and other non-physical assets that provide economic value to the firm. construct the Intangible Investment Restraint signal by calculating the year-over-year change in investment activity, scaled by the firm’s intangible asset base. Specifically, we compute $(IVCH(t) - IVCH(t-1)) / INTAN(t-1)$, where t denotes the current fiscal year. This measure captures the acceleration or deceleration in investment spending relative to the firm’s existing stock of intangible assets. A positive value indicates increasing investment intensity, while a negative value suggests the firm is restraining its investment activities relative to its intangible asset base. We calculate this signal annually using fiscal year-end values and require non-missing observations for both IVCH and INTAN variables. To ensure meaningful scaling, we exclude firm-year observations where lagged intangible assets equal zero or are negative.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the IIR signal. Panel A plots the time-series of the mean, median, and interquartile range for IIR. On average, the cross-sectional

mean (median) IIR is -0.39 (0.00) over the 1973 to 2024 sample, where the starting date is determined by the availability of the input IIR data. The signal’s interquartile range spans -0.01 to 0.01. Panel B of Figure 1 plots the time-series of the coverage of the IIR signal for the CRSP universe. On average, the IIR signal is available for 3.74% of CRSP names, which on average make up 4.35% of total market capitalization.

4 Does IIR predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on IIR using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high IIR portfolio and sells the low IIR portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short IIR strategy earns an average return of 0.23% per month with a t-statistic of 3.05. The annualized Sharpe ratio of the strategy is 0.43. The alphas range from 0.22% to 0.27% per month and have t-statistics exceeding 2.85 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios’ loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy’s most significant loading is 0.24, with a t-statistic of 4.51 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 372 stocks and an average market capitalization of at least \$1,079 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 13 bps/month with a t-statistics of 2.32. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-three exceed two, and for nine exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -8-29bps/month. The lowest return, (-8 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.16. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the

IIR trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in nineteen cases.

Table 3 provides direct tests for the role size plays in the IIR strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and IIR, as well as average returns and alphas for long/short trading IIR strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the IIR strategy achieves an average return of 30 bps/month with a t-statistic of 2.74. Among these large cap stocks, the alphas for the IIR strategy relative to the five most common factor models range from 30 to 37 bps/month with t-statistics between 2.65 and 3.31.

5 How does IIR perform relative to the zoo?

Figure 2 puts the performance of IIR in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the IIR strategy falls in the distribution. The IIR strategy’s gross (net) Sharpe ratio of 0.43 (0.35) is greater than 83% (93%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the IIR strategy (red line).² Ignoring trading costs, a \$1 invested in the IIR strategy

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides

would have yielded \$2.62 which ranks the IIR strategy in the top 8% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the IIR strategy would have yielded \$1.85 which ranks the IIR strategy in the top 7% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the IIR relative to those. Panel A shows that the IIR strategy gross alphas fall between the 49 and 71 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197306 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The IIR strategy has a positive net generalized alpha for five out of the five factor models. In these cases IIR ranks between the 67 and 84 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does IIR add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations.

Figure 5 plots a name histogram of the correlations of IIR with 208 filtered anomaly of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price IIR or at least to weaken the power IIR has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of IIR conditioning on each of the 208 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{IIR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{IIR}IIR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 208 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{IIR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 208 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 208 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on IIR. Stocks are finally grouped into five IIR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted IIR trading strategies conditioned on each of the 208 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on IIR and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the IIR signal in these Fama-MacBeth regressions exceed

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

-0.65, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on IIR is -0.45.

Similarly, Table 5 reports results from spanning tests that regress returns to the IIR strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the IIR strategy earns alphas that range from 21-22bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.71, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the IIR trading strategy achieves an alpha of 19bps/month with a t-statistic of 2.42.

7 Does IIR add relative to the whole zoo?

Finally, we can ask how much adding IIR to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the IIR signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$993.77, while \$1 investment in the combination strategy that includes IIR grows to \$1083.82.

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which IIR is available.

8 Conclusion

This study provides robust evidence that Intangible Investment Restraint (IIR) represents a meaningful signal for predicting cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that IIR maintains significant predictive power even after accounting for transaction costs and controlling for established risk factors and related anomalies.

The key findings reveal that a value-weighted long/short strategy based on IIR generates economically significant returns, with an annualized net Sharpe ratio of 0.35 and monthly abnormal returns of 19 basis points relative to the Fama-French five-factor model plus momentum. Notably, the signal’s robustness persists even when controlling for six closely related strategies from the factor zoo, including net external financing, asset growth, and accruals, yielding a monthly alpha of 19 basis points with a t-statistic of 2.42. This suggests that IIR captures unique information about firm value that is not fully explained by existing factors or related investment and financing anomalies.

The practical implications of these findings are substantial for both academic researchers and investment practitioners. The persistence of IIR’s predictive power after transaction costs indicates its potential viability as an implementable trading strategy. Moreover, the signal’s ability to generate alpha relative to both standard risk factors and conceptually related strategies suggests that firms’ restraint in intangible investments provides valuable information about future returns that is distinct from traditional measures of investment behavior and capital allocation efficiency.

Despite these compelling results, several limitations warrant consideration. First, while our analysis accounts for transaction costs, real-world implementation challenges such as market impact and capacity constraints may further erode returns, particularly as strategy adoption increases. Second, the economic mechanism un-

derlying the IIR anomaly requires further investigation to determine whether it represents a risk-based explanation or a behavioral mispricing that may be arbitrated away over time.

Future research should explore several promising avenues. Examining the time-varying nature of the IIR premium and its relationship with macroeconomic conditions could provide insights into the underlying economic drivers. Additionally, investigating the interaction between IIR and firm characteristics such as RD intensity, industry classification, and competitive dynamics may reveal important heterogeneity in the signal's effectiveness. Finally, extending the analysis to international markets would test the generalizability of our findings and potentially uncover market-specific factors that influence the relationship between intangible investment restraint and stock returns. Understanding whether the IIR anomaly persists across different regulatory environments and accounting standards would strengthen our conclusions about its fundamental nature and long-term sustainability as a return predictor.

Figure 1: Times series of IIR percentiles and coverage.
This figure plots descriptive statistics for IIR. Panel A shows cross-sectional percentiles of IIR over the sample. Panel B plots the monthly coverage of IIR relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on IIR. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197306 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the IIR strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197306 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and IIR

This table presents results for conditional double sorts on size and IIR. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on IIR. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high IIR and short stocks with low IIR. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197306 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	IIR Quintiles					IIR Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

	(4)	40	40	40	40	40	182	184	178	182	183	
(5)	37	37	37	37	37	1619	1259	1149	1153	1624		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the IIR with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the IIR trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 5: Distribution of correlations. This figure plots a name histogram of correlations of 208 filtered anomaly signals with IIR. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of IIR conditioning on each of the 208 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{IIR} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{IIR}IIR_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 208 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{IIR,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 208 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 208 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on IIR. Stocks are finally grouped into five IIR portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted IIR trading strategies conditioned on each of the 208 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on IIR. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{IIR} IIR_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Net external financing, Net debt financing, Change in equity to assets, Total accruals, Asset growth, Accruals. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Intercept	0.13 [5.52]	0.13 [5.28]	0.13 [5.28]	0.13 [5.18]	0.14 [5.70]	0.12 [4.96]	0.14 [5.51]

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the IIR trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{IIR} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Net external financing, Net debt financing, Change in equity to assets, Total accruals, Asset growth, Accruals. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197306 to 202406.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as IIR. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
