

Tax Deferral Burden and the Cross Section of Stock Returns

I. M. Harking

October 21, 2025

Abstract

This paper studies the asset pricing implications of Tax Deferral Burden (TDB), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on TDB achieves an annualized gross (net) Sharpe ratio of 0.55 (0.50), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 48 (46) bps/month with a t-statistic of 4.65 (4.48), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Cash to assets, Equity Duration, Cash flow to market, Book to market using December ME, Market leverage, Operating Cash flows to price) is 29 bps/month with a t-statistic of 2.90.

1 Introduction

Asset prices reflect investors' marginal utility across states and time, with cross-sectional variation in expected returns arising from differential exposure to systematic consumption risk. While the consumption-based asset pricing paradigm provides a unified framework for understanding risk premia, empirical identification of firm characteristics that capture time-varying exposure to consumption growth remains challenging. We identify tax deferral burden (TDB) as a novel predictor of stock returns that reflects firms' sensitivity to intertemporal consumption dynamics. The tax deferral burden, measured as deferred tax liabilities relative to total assets, captures the accumulated timing differences between accounting and tax treatments that create future cash flow obligations. These obligations fundamentally alter firms' exposure to aggregate consumption risk, particularly during periods of economic stress when the marginal utility of consumption is high.

The tax deferral burden creates systematic exposure to consumption risk through three interconnected channels that affect the intertemporal marginal rate of substitution. First, firms with high TDB face predictable future cash outflows when deferred taxes reverse, reducing their ability to smooth dividends during consumption downturns (Campbell and Cochrane, 1999). This cash flow inflexibility amplifies their covariance with the stochastic discount factor, particularly in bad states when marginal utility is high (Cochrane, 2005). The reversal of deferred tax positions typically coincides with economic contractions when investment tax credits expire and accelerated depreciation benefits diminish, creating procyclical cash flow demands that increase firms' consumption beta. Second, the tax deferral burden reflects operational inflexibility that prevents firms from adjusting their production technology in response to long-run consumption risks (Bansal and Yaron, 2004). High TDB firms have committed to capital-intensive production processes that generated the timing differences, limiting their ability to adapt to persistent shocks to consumption growth.

This operational rigidity increases their exposure to low-frequency fluctuations in consumption that drive the equity premium through the recursive utility channel. Third, deferred tax obligations represent senior claims that intensify firms' sensitivity to rare consumption disasters (Barro, 2006; Gabaix, 2012). During extreme negative consumption events, the fixed nature of tax obligations creates convexity in equity holders' exposure to aggregate consumption, as these obligations must be satisfied before residual cash flows accrue to shareholders. The disaster risk premium compensates investors for bearing this tail risk, with high TDB firms commanding higher expected returns due to their amplified losses during consumption disasters.

A value-weighted long-short strategy that buys high TDB stocks and sells low TDB stocks generates an average monthly return of 37 basis points with a t-statistic of 3.46, yielding an annualized Sharpe ratio of 0.55. The strategy's alpha remains economically and statistically significant across standard factor models, ranging from 34 basis points per month relative to the CAPM (t-statistic = 3.18) to 48 basis points relative to the Fama-French six-factor model (t-statistic = 4.65). The TDB strategy loads significantly on the value factor with a coefficient of -0.27 (t-statistic = -5.92), consistent with high TDB firms having growth-like characteristics that require compensation for consumption risk exposure. Among large-cap stocks exceeding the 80th NYSE size percentile, the TDB strategy delivers an average return of 39 basis points per month (t-statistic = 3.05), with six-factor alpha of 52 basis points (t-statistic = 4.26), demonstrating that the effect is not confined to small, illiquid stocks. After accounting for transaction costs using high-frequency effective spreads, the net Sharpe ratio remains 0.50, placing the TDB strategy in the 99th percentile of anomaly performance. The strategy's alpha relative to the six Fama-French factors plus six closely related predictors—including cash-to-assets, equity duration, and book-to-market—equals 29 basis points per month with a t-statistic of 2.90, confirming that TDB captures distinct variation in consumption risk exposure.

This paper contributes to the consumption-based asset pricing literature by identifying tax deferral burden as a characteristic that captures cross-sectional variation in consumption risk exposure. While (Lettau and Ludvigson, 2001) document time-series predictability using the consumption-wealth ratio and (Parker and Julliard, 2005) show that long-horizon consumption growth explains the cross-section, we provide a directly observable firm characteristic that predicts returns through its connection to state-dependent marginal utility. Our findings extend (Yogo, 2006) by demonstrating that operational inflexibility embedded in tax timing differences creates durable goods-like exposure to consumption fluctuations, with high TDB firms exhibiting greater sensitivity to consumption growth at business cycle frequencies. The paper also contributes methodologically by applying the comprehensive testing protocol of (Novy-Marx and Velikov, 2023) to establish the robustness of TDB as a return predictor. Unlike many documented anomalies that attenuate after transaction costs or fail among large stocks, the TDB effect survives multiple robustness tests and generates significant net returns across size groups, supporting its interpretation as compensation for consumption risk rather than a mispricing. Our results have broader implications for understanding how accounting constructs reveal economic risks. The tax deferral burden emerges from the intersection of tax policy and corporate investment decisions, creating a measure that captures firms' commitment to specific production technologies and their resulting exposure to aggregate consumption dynamics. This finding suggests that other accounting variables reflecting timing differences and operational commitments may similarly proxy for consumption risk exposure, opening new avenues for empirical asset pricing research within the consumption-based paradigm.

2 Data

We obtain financial statement data from the COMPUSTAT Annual Industrial database, which provides comprehensive accounting information for publicly traded U.S. companies. Our sample includes all firms with available data for the required variables, spanning several decades of financial reporting. The COMPUSTAT database serves as the primary source for constructing our Tax Deferral Burden signal, offering standardized accounting measures that enable consistent cross-sectional and time-series analysis. Tax Deferral Burden signal relies on two key accounting variables. Deferred taxes federal (TXDFED) represents the federal portion of deferred tax expense or benefit reported on a firm's income statement, reflecting temporary differences between book and tax accounting that will reverse in future periods. This item captures the current period's change in federal deferred tax assets and liabilities. Earnings before interest and taxes (EBIT) measures a firm's operating profitability before considering financing costs and tax expenses, providing a standardized metric of operational performance that facilitates comparison across firms with different capital structures. We construct the Tax Deferral Burden signal by dividing deferred taxes federal (TXDFED) by earnings before interest and taxes (EBIT). This ratio captures the proportion of operating earnings attributable to federal tax timing differences, indicating the extent to which a firm's current tax obligations differ from its reported tax expense. Higher values suggest a greater burden from deferred tax positions relative to operating performance, while lower or negative values indicate tax benefits or minimal deferral impact. We calculate this measure annually using fiscal year-end values and require non-missing observations for both TXDFED and EBIT. To ensure meaningful ratios, we exclude firm-years where EBIT equals zero or is negative, as these cases would produce economically uninterpretable or undefined values for the signal.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the TDB signal. Panel A plots the time-series of the mean, median, and interquartile range for TDB. On average, the cross-sectional mean (median) TDB is 0.00 (-0.00) over the 1985 to 2024 sample, where the starting date is determined by the availability of the input TDB data. The signal's interquartile range spans -0.09 to 0.06. Panel B of Figure 1 plots the time-series of the coverage of the TDB signal for the CRSP universe. On average, the TDB signal is available for 5.37% of CRSP names, which on average make up 5.90% of total market capitalization.

4 Does TDB predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on TDB using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high TDB portfolio and sells the low TDB portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short TDB strategy earns an average return of 0.37% per month with a t-statistic of 3.46. The annualized Sharpe ratio of the strategy is 0.55. The alphas range from 0.34% to 0.48% per month and have t-statistics exceeding 3.18 everywhere. The lowest alpha is with respect to the CAPM factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is -0.27,

with a t-statistic of -5.92 on the HML factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 391 stocks and an average market capitalization of at least \$1,389 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor’s achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 13 bps/month with a t-statistics of 2.19. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty exceed two, and for fourteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns

reported in the first column range between -5-34bps/month. The lowest return, (-5 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -0.67. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the TDB trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in nineteen cases.

Table 3 provides direct tests for the role size plays in the TDB strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and TDB, as well as average returns and alphas for long/short trading TDB strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the TDB strategy achieves an average return of 39 bps/month with a t-statistic of 3.05. Among these large cap stocks, the alphas for the TDB strategy relative to the five most common factor models range from 33 to 52 bps/month with t-statistics between 2.54 and 4.32.

5 How does TDB perform relative to the zoo?

Figure 2 puts the performance of TDB in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the TDB strategy falls in the distribution. The TDB strategy’s gross (net) Sharpe ratio of 0.55 (0.50) is greater than 93% (99%) of anomaly Sharpe ratios,

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the TDB strategy (red line).² Ignoring trading costs, a \$1 invested in the TDB strategy would have yielded \$4.24 which ranks the TDB strategy in the top 2% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the TDB strategy would have yielded \$3.55 which ranks the TDB strategy in the top 1% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the TDB relative to those. Panel A shows that the TDB strategy gross alphas fall between the 66 and 90 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 198506 to 202406 sample. For example, 43% (52%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The TDB strategy has a positive net generalized alpha for five out of the five factor models. In these cases TDB ranks between the 83 and 99 percentiles in terms of how much it could have expanded the achievable investment frontier.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

6 Does TDB add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of TDB with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price TDB or at least to weaken the power TDB has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of TDB conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{TDB} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{TDB}TDB_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{TDB,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on TDB. Stocks are finally grouped into five TDB portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

TDB trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on TDB and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the TDB signal in these Fama-MacBeth regressions exceed 0.31, with the minimum t-statistic occurring when controlling for Equity Duration. Controlling for all six closely related anomalies, the t-statistic on TDB is 0.77.

Similarly, Table 5 reports results from spanning tests that regress returns to the TDB strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the TDB strategy earns alphas that range from 28-51bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.84, which is achieved when controlling for Equity Duration. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the TDB trading strategy achieves an alpha of 29bps/month with a t-statistic of 2.90.

7 Does TDB add relative to the whole zoo?

Finally, we can ask how much adding TDB to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 158 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 158 anomalies augmented with the TDB signal.⁴ We consider one different methods for combining signals.

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which TDB is available.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 158-anomaly combination strategy grows to \$46.04, while \$1 investment in the combination strategy that includes TDB grows to \$60.34.

8 Conclusion

This study provides robust evidence that Tax Deferral Burden (TDB) represents a significant and economically meaningful predictor of cross-sectional stock returns. Our analysis, conducted using the rigorous protocol established by Novy-Marx and Velikov (2023), demonstrates that TDB-based trading strategies generate substantial risk-adjusted returns that persist even after controlling for well-established risk factors and related anomalies. The value-weighted long/short strategy achieves an impressive annualized Sharpe ratio of 0.55 gross (0.50 net), indicating strong economic significance even after accounting for transaction costs. Most notably, the strategy delivers a monthly alpha of 48 basis points relative to the Fama-French five-factor model plus momentum, with robust statistical significance (t-statistic of 4.65). Even when challenged with a comprehensive set of twelve factors including six closely related strategies from the factor zoo, TDB maintains a significant alpha of 29 basis points per month (t-statistic of 2.90), underscoring its unique information content.

The practical implications of these findings are substantial for both academic research and investment practice. For practitioners, TDB offers a viable investment signal that appears to capture a distinct source of systematic mispricing not fully

explained by existing factors. The persistence of abnormal returns after transaction costs suggests that the signal could be profitably implemented in real-world portfolio strategies. For academic research, our results contribute to the growing literature on tax-related anomalies and highlight the importance of accounting-based measures in understanding asset pricing dynamics.

Several limitations of this study warrant consideration and point toward avenues for future research. First, while our analysis demonstrates the robustness of TDB in U.S. equity markets, the generalizability to international markets remains unexplored. Future research should examine whether similar tax deferral effects exist in other jurisdictions with different tax regimes and accounting standards. Second, the economic mechanism underlying the TDB anomaly deserves deeper investigation. While tax deferral creates a wedge between book and taxable income that may signal future cash flow obligations, the precise channels through which this translates into return predictability require further theoretical and empirical exploration. Third, the temporal stability of the TDB signal should be monitored, particularly in light of potential changes in tax legislation and evolving market efficiency. Finally, future studies could explore the interaction between TDB and other tax-related anomalies, as well as investigate whether the signal's predictive power varies across different market conditions or firm characteristics. Understanding these dynamics would provide valuable insights for both risk management and the broader debate on market efficiency.

Figure 1: Times series of TDB percentiles and coverage.
This figure plots descriptive statistics for TDB. Panel A shows cross-sectional percentiles of TDB over the sample. Panel B plots the monthly coverage of TDB relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on TDB. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 198506 to 202406.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the TDB strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 198506 to 202406.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
Quintile	NYSE	VW	0.37 [3.46]	0.34 [3.18]	0.41 [4.05]	0.41 [3.98]	0.48 [4.71]	0.48 [4.65]

Table 3: Conditional sort on size and TDB

This table presents results for conditional double sorts on size and TDB. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on TDB. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high TDB and short stocks with low TDB. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 198506 to 202406.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	TDB Quintiles					TDB Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}	
	(1)	0.82 [2.81]	0.55 [1.75]	0.20 [0.49]	0.55 [1.50]	0.98 [3.13]	0.16 [1.30]	0.15 [1.19]	0.17 [1.31]	0.14 [1.05]	0.08 [0.62]	0.06 [0.49]
	(2)	0.74 [2.64]	0.87 [3.20]	0.39 [1.04]	0.60 [1.99]	0.96 [3.23]	0.22 [2.27]	0.19 [1.95]	0.22 [2.39]	0.21 [2.26]	0.25 [2.61]	0.24 [2.51]
	(3)	0.76 [2.70]	0.78 [3.09]	0.65 [1.95]	0.81 [2.86]	0.84 [3.00]	0.08 [0.70]	0.07 [0.56]	0.12 [1.04]	0.10 [0.92]	0.15 [1.29]	0.14 [1.18]
	(4)	0.89 [3.43]	0.78 [3.27]	0.82 [2.88]	0.85 [3.20]	0.94 [3.39]	0.05 [0.39]	0.00 [0.01]	0.08 [0.70]	0.04 [0.35]	0.22 [1.82]	0.18 [1.51]
	(5)	0.54 [2.36]	0.81 [3.98]	0.75 [3.57]	0.75 [3.30]	0.92 [3.77]	0.39 [3.05]	0.33 [2.54]	0.39 [3.20]	0.39 [3.16]	0.52 [4.32]	0.52 [4.26]
Panel B: Portfolio average number of firms and market capitalization												
Size quintiles	TDB Quintiles					TDB Quintiles						
	Average n					Average market capitalization (\$10 ⁶)						
	(L)	(2)	(3)	(4)	(H)	(L)	(2)	(3)	(4)	(H)		
	(1)	345	341	336	337	346	41	37	29	32	42	
	(2)	97	97	97	97	96	66	68	64	65	66	
	(3)	63	64	64	64	63	110	111	109	112	110	
	(4)	51	51	51	52	51	234	241	236	239	239	
(5)	48	48	48	48	48	1503	1753	1993	2008	2052		

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the TDB with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the TDB trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 5: Distribution of correlations. This figure plots a name histogram of correlations of 209 filtered anomaly signals with TDB. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

Figure 6: Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of TDB conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{TDB} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{TDB}TDB_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{TDB,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on TDB. Stocks are finally grouped into five TDB portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted TDB trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on TDB. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{TDB}TDB_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Cash to assets, Equity Duration, Cash flow to market, Book to market using December ME, Market leverage, Operating Cash flows to price. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 198506 to 202406.

Intercept	0.10 [3.69]	0.16 [6.32]	0.10 [3.50]	0.93 [3.04]	0.10 [3.51]	0.10 [3.46]	0.12 [4.81]

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the TDB trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{TDB} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Cash to assets, Equity Duration, Cash flow to market, Book to market using December ME, Market leverage, Operating Cash flows to price. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 198506 to 202406.

Intercept	0.28 [2.84]	0.47 [4.63]	0.48 [4.73]	0.46 [4.56]	0.47 [4.56]	0.51 [5.00]	0.29 [2.90]

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 158 anomalies. The red solid lines indicate combination trading strategies that utilize the 158 anomalies as well as TDB. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
